CORPULENCE (*corpus*, a body, and *lentus*, thick).—An undue accumulation of fat in the body. See **OBESITY**.

CORPUSCLE (*corpusculum*, a little body).—In physiology and pathology this word is generally used as synonymous with cell. See **CELL**.

CORPUS STRIATUM, Lesions of.—The corpus striatum of English anatomy and pathology comprises various structures which have received special names, viz.: the *nucleus caudatus*, or intra-ventricular nucleus, which is exposed to view by laying open the lateral ventricle; the *nucleus lenticularis*, or extra-ventricular nucleus, consisting of three divisions, and subjacent to the convolutions of the Island of Reil, together with part of the *internal capsule*, or peduncular expansion, which forms part of the 'projection system' between the cortex and crus cerebri.

This differentiation is considered necessary, as it is believed that the effects of lesion of the corpus striatum will differ according to the part involved, although up to the present it cannot be said that this has been conclusively established. This is not to be wondered at considering the excessive rarity of lesions which have an exact anatomical and functional circumscription.

Physiological experiment, while thoroughly in harmony with clinical and pathological observations respecting the effects of lesion of the corpus striatum, has not succeeded in defining the functions of its several parts, if such differentiation exists, with any degree of precision. The statements made by some physiologists on the point, do not seem to the writer to rest on any satisfactory basis.

The corpus striatum is especially liable to lesion from embolism or rupture of its blood-vessels. These are furnished principally by the middle cerebral artery, which in the first part of its course sends off numerous straight twigs, which sink into the anterior perforated space, and supply this ganglion and the adjacent part of the optic thalamus. Owing to their position, and direction as regards the main current, they are easily ruptured or blocked up, and owing to their being of the nature of 'end arteries,' and almost destitute of anastomoses with other cerebral arteries, embolism rapidly leads to softening of the regions which they nourish.

SYMPTOMS.—The symptoms of lesion of the corpus striatum may be divided into three groups or stages.

First stage.—This includes certain symptoms which are more or less transient, and depend chiefly on the suddenness of the lesion and functional disturbance of other parts.

To the latter belong the symptoms usually accompanying an apoplectic seizure (apoplexy), as also the loss or diminution of sensation on the opposite side of the body, which sometimes occurs in consequence of pressure on, or functional interference with, the sensory tracts of the in-

ternal capsule by effusion into the corpus striatum. The symptoms due to the suddenness of the lesion of the corpus striatum as such, are complete paralysis of every voluntary movement on the opposite side of the body, occasionally varied by convulsive spasms of the paralysed side, and conjugate deviation of the head and eyes towards the sound side. This latter symptom is due to the centres for the head and eyes of the opposite hemisphere suddenly losing their antagonists. The temperature of the paralysed side is as a rule higher than that of the sound side. The total paralysis and flaccidity of the opposite side of the body, and conjugate deviation of the head and eyes, are transient symptoms, lasting from a few hours to a day or two.

Second stage.—This stage includes those symptoms which continue for a variable period, after those depending on the suddenness and disturbing effect of the lesion have passed off. They constitute the common type of hemiplegia or paralysis of voluntary motion on the side opposite the lesion. The face, arm, and leg, and to a certain extent the thoracic and abdominal muscles on the one side of the body, are affected. The paralysis does not affect all these parts equally. As a general rule it may be stated that those movements are most affected which are most independent of those of the opposite side, and which are most complex and delicate.

Hence the movements of the hand and arm are more affected than those of the face or leg owing to the fact that these latter are more commonly exercised in associated or alternating action with those of the other side. The facial paralysis is most marked in the lower facial region. The orbicularis palpebrarum is more or less parietic, but never paralysed to the extent which occurs in Bell's or true facial paralysis, depending on lesion of the portio dura. The angle of the mouth on the paralysed side hangs lower, and the tongue deviates slightly to the paralysed side. The weakness of the facial muscles is best brought out when the patient smiles or tries to whistle. The face then becomes drawn to the sound side. While some volitional control may have been acquired over the leg, the hand and arm remain perfectly motionless.

In the process of recovery, the leg recovers before the arm, and as a rule the recovery proceeds from the proximal to the distal end of the limb, the shoulder and hip movements being regained before those of the hand or foot. The flexors regain their power before the extensors.

The sensibility of the paralysed parts is unimpaired; the superficial reflexes are diminished, the deep (tendon) reflexes increased.

The faradic contractility of the muscles is unimpaired, occasionally rather increased than diminished.

The muscles do not undergo atrophy except by disuse.

The temperature of the paralysed limbs, which at first is usually increased, is generally found to be lower than that of the sound side, to the extent of a degree, more or less.

Recovery may take place from all the symptoms of this stage, within a period varying from

weeks to months, or the patient may pass into the third stage.

Third stage.—The special symptoms of this stage are the occurrence of what is termed 'late rigidity' in the paralysed limbs, a condition of evil import. This rigidity shows itself most frequently in the arm, but it is common enough in both limbs. The rigidity affects the flexors more particularly, and causes the limb to assume a position in which the flexors predominate. It is variable in degree and at first is capable of being overcome. At first also, it is remittent, tending to give way when the patient abstains from volitional efforts or from excitement, and seems almost gone on waking from sleep or when the patient yawns or stretches himself.

Gradually it assumes a more intense form, and the limb becomes permanently fixed and rigid.

After death, this condition is found to coincide with descending sclerosis of the motor tracts of the brain and spinal cord. The degeneration proceeds from the seat of lesion downwards through the crus, pons, pyramid of the same side, and then across to the posterior part of the lateral column of the spinal cord on the paralysed side. Frequently also, a similar track of degeneration is found on the inner aspect of the anterior column of the spinal cord, on the same side as the brain-lesion (Charcot, Türek, &c).

Even during the rigid stage, there is, as a rule, no trophic degeneration of the muscles or annihilation of faradic contractility, though the muscles waste from disuse unless artificially stimulated. But in some rare instances as Charcot has shown, the secondary degeneration invades the anterior cornua of the spinal cord, in which case amyotrophy or trophic degeneration of the muscles ensues.

There is no recovery from this condition.

Variations and complications.—Though general hemiplegia of the opposite side, without affection of sensation, is the type of disease of the corpus striatum, certain variations and complications have been observed, some of which still require elucidation.

When sensation is permanently affected along with voluntary motion, we have reason to regard the lesion as not confined to the corpus striatum, but as implicating also the posterior part of the internal capsule and the thalamus, an occurrence by no means rare. When the lesion affects only the grey matter of the nucleus caudatus, it is said that the hemiplegia is as a rule comparatively slight and transitory.

Similar affection of the nucleus lenticularis is said to produce more marked paralysis than that caused by affection of the nucleus caudatus, but also not of a permanent kind. When, however, the lesion causes rupture of the anterior two-thirds of the internal capsule, the hemiplegia is most marked and most enduring. It is this lesion only which gives rise to secondary degeneration of the motor tracts and permanent rigidity.

Cases are on record in which lesions of the corpus striatum have given rise, not to general hemiplegia of the opposite side, but to

plegia, such as paralysis of the face or of one or other limb. We cannot yet say whether the lesions in these cases affected specially differentiated centres or medullary fibres, but that such may be the case is not impossible, though the subject requires investigation.

Cases are also on record of paralysis occurring on the same side of the body as the lesion. The real existence and explanation of such exceptional occurrences are still *sub judice*, and though various explanations may be suggested, it is well to wait for further instances, carefully investigated by accurate modern methods, before pronouncing definitely on the question.

TREATMENT.—It is unnecessary to discuss the treatment of lesions of the corpus striatum, as this is considered under the head of the various diseases of the brain. D. FERRIER.

CORRELATION.—This term is used in medicine almost exclusively in reference to the etiology of disease, and in this relation principally in regard to the zymotic diseases. The term 'correlation of the physical forces' may be taken as implying that the several forces are capable of being converted into or of giving place to one another when they are permitted to act under certain conditions, and that they are all related to a common cause. It is very much the same idea that is implied by the term 'Correlation of the Zymotic Diseases,' a subject which has recently been discussed in a separate work by A. Wolff.

It is contended that the several contagious diseases of a general type (the exanthemata) do not, necessarily and in all cases, reproduce their like; but that occasionally, the contagious particles thrown off from the same sick person suffering from some one of the diseases (e.g. scarlatina) may suffice to engender one or more different kinds of disease, according to the mode in which this matter operates—that is according as it may be swallowed, taken into the system through the pulmonary surface, or through some other mucous membrane or skin abrasion. These diseases are said to be correlated, therefore, on account of this assumed relation to a common cause—a specific contagium. According to this notion the seat of primary action and the constitutional condition of the patient are factors which largely influence the form of disease which will ultimately manifest itself as a result of the contact of any given contagium. This view has at present scarcely passed beyond the stage of an ingenious speculation—though it is one which is by no means unworthy of further attention.

Diseases may be said to be correlated also when they are severally related to the same cause acting with different degrees of intensity. Thus it is held by some epidemiologists that the plague is only a malignant form of typhus; that yellow fever is due to a more intense form or action of the same poison as suffices at other times to engender intermittent or remittent fever; and that summer diarrhoea, cholera, and cholera are also but different manifestations of one common though variable cause.

Similarly it is held by many surgeons that ordinary surgical fever, pyæmia, and septicæmia

are correlated effects. They maintain that the appearance of one or other of these morbid states after a surgical operation is dependent in the main upon differences in the constitutional condition of their patients, and, moreover, that these forms of disease are further linked to one another by numerous intermediate states. This point of view has been both strengthened and extended of late, by some of the experimental researches of Dr Burdon Sanderson. He found that the subcutaneous injection of different portions of the same inflammatory product, executed at the same time, would often produce quite different effects upon different animals of the same species. At one time a typical septicæmia proved rapidly fatal, at another a slower pyæmic process was established, whilst in a third animal the still more chronic process of so-called tuberculosis was set up. Here we get out of the region of speculation into that of fact.

The term correlation is only applicable to communicable diseases, otherwise its leading signification, viz. convertibility, could not be fulfilled. Hence it is that though very many diseases may arise from the operation upon different individuals of some common cause (such as exposure to cold), the maladies which may result from such a cause no one would think of speaking of as correlated.

H. CHARLTON BASTIAN.

CORROSIVE SUBLIMATE, Poisoning by. See MERCURY, Poisoning by.

CORYZA (κόρυφα, a running from the head).—A synonym for nasal catarrh. See CATARRH.

COUGH.—SYNON.: *Tussis*; Fr. *Toux*; Ger. *Husten*.

DESCRIPTION.—The act of coughing consists in one or more abrupt forcible expirations, accompanied by contraction of the glottis. First a deep inspiration is taken, the glottis is closed for a moment, and then it is opened by the pressure of the air forced out by the combined action of the thoracic and abdominal expiratory muscles. With the air thus suddenly expelled, any foreign matter that may be in the larynx or bronchi is driven into the pharynx or the mouth.

ÆTIOLOGY.—The immediate cause of cough is the presence of an irritant, mechanical or sympathetic, affecting the surface of the air-tubes or the nerves that supply them, and it is the object of the cough to remove this source of irritation.

The sensibility of the respiratory surfaces is greatest at the commencement—the glottis being an ever-watchful janitor. It may be increased by congestion or inflammation, or by the continued act of coughing. Even the mere inhalation of cool or dry air may, in asthma or bronchial congestion, be sufficient to excite cough. The result of the irritation is to increase the natural secretion, and to alter its characters (*see* EXPECTORATION).

Cough may be due to numerous reflex causes, such as gastric irritation, ear-disorder, or aneurismal or other pressure on the vagus, recurrent, or sympathetic nerves. The act may also be caused by a long uricæ or enlarged tonsil; a granular state of the pharyngeal or laryngeal mucous membrane; polypi or other foreign

bodies in the larynx, trachea, or even in the external auditory meatus, various affections of the bronchial tubes—*e.g.*, undue dryness, hyperæmia, alteration in the quality or quantity of the bronchial secretion, or inflammatory affections; inflammation of the lung or pleura; or tubercle, cancer, or other growths in or near the lung.

Diagnosis.—Cough is not a disease to be treated, but a symptom to be traced to its source. An inspection of the pharynx and larynx and a physical examination of the chest will generally suffice to detect the cause.

The character of the cough is often quite pathognomonic—*e.g.*, the 'whoop' of whooping cough; the 'bark' of hysteria; the catching, painful cough of pleurisy; the slight 'hack' of early phthisis, and the equally distinctive cough of advanced phthisis with laryngeal ulceration; the loud clanging cough due to pressure on the trachea or laryngeal nerves; the spasmodic, suffocative cough of asthma.

The 'tightness' or 'looseness' of cough, indicating the absence or presence of secretion, is a valuable guide in diagnosis and treatment.

The *absence of cough* is no proof of the absence of serious lesion: while the presence of a few granulations in the lung is often productive of incessant and uncontrollable cough, long-continued destructive disease may exist without it.

Treatment.—Before prescribing for a cough it is of course essential to ascertain its cause, and the simplest and most innocuous remedies should be first used. The routine treatment of cough by sedatives is as injurious as is their use in diarrhoea. The secretions which ought to be removed are thus, in either case, locked up, and the irritation, which would have been transient, becomes established.

If the tonsils are found much enlarged, or the uvula pendulous and irritating the epiglottis, caustics or the guillotine will remove the evil. If a granular state of the pharyngeal membrane, dependent on torpid or engorged abdominal viscera, gout, or hepatic obstruction, exists, it may be treated by local astringents and general deobstruents.

A lax or congested state of the laryngeal membrane, due to overwork of voice, or the undue direction of attention to the vocal apparatus (clergyman's sore-throat), is best treated, according to the writer's experience, by the local application of iodine dissolved in spirit and olive oil. Undue dryness, simple hyperæmia, or hyperæsthesia of the respiratory mucous tract, may often be relieved by the act of sipping and slowly swallowing cold water, or the decoction of Iceland moss, fruit lozenges, gum arabic, liquorice, or linseed tea. Sucking ice or inhaling steam is very often all that is needed. In the early stage of catarrhal sore-throat, chlorate of potash in crystal, or in the form of lozenge, should not be neglected. The use of glycerine of tannin, or nitrate of silver dissolved in glycerine (half a drachm to one ounce) is of more service in relaxed throat than alum or tannin gargle; indeed, the free use of well-selected lozenges has rendered the employment of gargles well-nigh obsolete. The former can be constantly, the latter but seldom applied.

Medical treatment.—If it is desired to in-

crease the fluidity of the secretion, squill or ipecacuanha may be used, or better still, tartar emetic in small doses, which is best given in effervescence with ammonia and citric acid. It must not be forgotten that syrups and nauseating expectorants are apt to do harm by enfeebling or disturbing digestion. Tincture of acacia in three-drop doses is often of value in allaying irritable cough, especially when fever is present. Gelsemium is the novel remedy for the same purpose. Of the direct sedatives, morphia is the most valuable; it proves of service in very small doses, $\frac{1}{4}$ -gr. in a lozenge being often adequate. Conium, with or without morphia, suits some persons; hydrocyanic acid still more; and Indian hemp is also of value. The bromides, in combination with chloral, have recently gained great repute; the latter should be given with caution. The power of the bromide of ammonium in allaying spasmodic cough is remarkable. An emetic of ipecacuanha, sulphate of zinc, or mustard may be useful in relieving cough, by expelling secretion when this has accumulated in large quantity. If cough causes vomiting, food should be taken in small quantities, fluids should be limited, and a little capsaicum or speed brandy 'stays the stomach.'

External applications.—The use of counter-irritants must not be neglected. In the inflammatory stage of bronchitis, for instance, linseed and mustard poultices, and in the later stages, iodine or croton oil are of great use. The application of a small blister or vesicating fluid is a remedy not to be forgotten in some cases.

Inhalations.—Infusion of hops as an inhalation is a useful calumative; iodine is indicated in relaxed conditions in strumous subjects. Chloroform (10 to 15 minims) mixed with Eau de Cologne, and inhaled from a handkerchief, is useful in other cases. By means of the spray-inhaler, many non-volatile preparations may be applied to the respiratory passages. A solution of carbonate of soda is very useful in liquefying tenacious secretion. Tannic acid, alum, perchloride of iron, and nitrate of silver, are all valuable. Of sedatives, henbane, conium, camphor; and of antiseptics, sulphurous and carbolic acids are serviceable as inhalants. In chronic granular disease of the pharyngeal and laryngeal mucous membranes, the sulphurous waters of Aix-la-Chapelle, Aix-les-Bains, and St. Saviour in the Pyrenees, when inhaled in an atomised state, are of distinct service.

Patients may be thus *taught how to cough*:—Try to suppress the inclination, until the secretion that causes the cough is within reach, then take a deep and deliberate inspiration, and the accumulated phlegm is removed at a single effort. By inhaling steam from a hot sponge or basin of boiling water on first waking from sleep, the inspissated secretion, which is apt to be difficult to move, may be easily loosened and expelled. An ipecacuanha lozenge may serve a similar purpose.

E. SYMES THOMPSON.

COUNTER-INDICATION. See CONTRA-INDICATION.

COUNTER-IRRITANTS.—The term counter-irritation implies any irritation specially established with a view to disperse,

abstract, or remove certain morbid processes which may be going on in a more or less remote part of the system. The substances employed in establishing this state are called counter-irritants, and may be classified as follows, according to degree of action:—1. Rubefacients; 2. Epispastics, vesicants, or blistering agents; 3. Pustulants.

Although some therapeutists have of late been disposed to question the value of counter-irritants, on the theoretical ground of inability to explain their mode of action, yet there is not wanting evidence, both from clinical observation and physiological experiment, that irritation in one part of the body may affect the functions and nutrition of other parts. That stimulation of the vessels of the surface can influence decidedly the circulation of deeper parts has been demonstrated by Dr. Brown-Séquard: for he found that irritation of the skin of the back, over the kidneys, caused a contraction of the arteries supplying those organs. From this experiment we can understand how a blister may relieve a sudden internal congestion in the lungs or brain, and how it may act in restoring tone to dilated and paralysed capillaries.

Remission and derivation are both examples of counter-irritation. In the first, the induced morbid action is set up in a part remote from the primary disease, as when mustard poultices are applied to the feet in an attack of apoplexy, in the second, derivative action is set up in the neighbourhood of the primary malady, as when a blister is placed on the back of the neck for the relief of cerebral disorder.

Rubefacients.—*Action.*—These remedies, applied to the skin, produce local warmth and redness from increased flow of blood in the cutaneous vessels. The local hyperæmia thus induced subsides gradually on ceasing to employ the rubeficient; but sometimes, when the action of this has been prolonged, the epidermis may peel off, and more or less local soreness remain. Rubeficients are usually quick in action, their local after-effects are trifling; and they may, therefore, be applied without injury over a large extent of surface.

Enumeration and Application.—Examples of rubeficients are found in Ammonia and Ammoniacal Liniments or Embrocations; Mustard Plasters and Liniment; Volatile Oil of Mustard, Oils of Turpentine and Cajuput, and Iodine. Hot water is at times applied on a sponge or flannel to produce a speedy counter-irritant and derivative effect in relieving sudden internal congestion and spasm, as in the early stage of croup, laryngitis, and laryngismus stridulus. The Cataplasmata Sinapis, or mustard poultices, is a useful and rapidly-acting rubeficient in inflammation, spasm, and neuralgic pain. Dr. Garrod recommends a very useful sinapism, made by mixing 10 minims of volatile oil of mustard with 1 oz of spirit of camphor, and sprinkling this on impermeable piline. Rigollot's mustard leaves, and the Charta Sinapis or mustard-paper of the Pharmacopœia, applied to the skin, produce a speedy rubefaction of the surface. Vinegar should not be added to mustard poultices; but by mixing some oil of turpentine or a little powdered capsicum in a mustard poultice, its

rapidity of action as a stimulant and rubeficient can be greatly increased. Where, on the other hand, a gentle stimulation with warmth and moisture to the surface are desired, as in some cases of pneumonia, a linseed-meal poultice may be used, with its surface sprinkled lightly over with mustard-meal. Generally twenty minutes is as long as an ordinary mustard poultice can be safely borne on the skin. In persons who have a very delicate skin, a layer or two of muslin should be placed between the mustard application and the surface of the body. In applying mustard poultices to those who are unconscious of pain, caution is necessary, for it has happened that the poultice being left on for a long time has produced dangerous ulceration and sloughing of the surface. A mustard foot-bath is at times employed with a view to a revulsive and counter-irritant effect. To prepare a mustard bath, two table-spoonfuls or more of mustard should be tied in a cloth, and agitated well with cold water; then hot water may be added to make the bath. It is found by experiment that cold water extracts the active principle or volatile oil of mustard far better than very hot water does.

Uses.—Rubeficients are used in chronic inflammation and irritation of the mucous surfaces, as in bronchitis, and irritation about the air-passages. Troublesome cough, in cases of phthisis, is often relieved by applying tincture of iodine, or acetic acid and turpentine liniment, to the chest. Rubeficients are of service in removing lingering irritation about a joint, their use also tending to promote the absorption of chronic thickening or effusion in the joint; but friction with a rubeficient liniment over a joint must not be employed till all active inflammatory action has entirely ceased. Various degrees of persistent counter-irritation may be maintained by applying, after the skin has been well cleansed with soap and water, the Emplastrum Picis or Emplastrum Calofaciens of the Pharmacopœia. A mustard plaster applied to the nape of the neck has proved useful in cases of irritable brain with sleeplessness. The same application made to the foot or great toe is a valuable revulsive where gout attacks more important organs. A mustard plaster has the advantage over a blister in rapidity of rubeficient action; and, from the sharp pain caused, the mustard plaster is preferable when it is a matter of moment to rouse one who is in a state of lethargy or torpor from narcotic poisoning by opium, or alcohol, or from coma in the course of a fever. Where we wish to exercise a prolonged action over chronic inflammation in an organ, we should use a blister rather than a sinapism.

Vesicants, Epispastics, or Blistering Agents.—*Action.*—A blister acts primarily as a rubeficient and powerful stimulant to the cutaneous vessels. The papillæ of the skin become reddened and raised; minute vesicles soon appear on these elevations; and these, gradually coalescing, form a bleb, or large vesicle, containing an albumino-fibrinous fluid.

Enumeration and Application.—The agent most commonly employed for blistering purposes is Cantharis or Spanish fly, in the several preparations to be found in the Pharmacopœia; but there are other agents that have been used for a

similar object. Glacial Acetic Acid applied to the skin produces intense redness and pain, with rapid vesication, but its action may extend deeply as a caustic, and cause a troublesome sore. Liquor Ammoniac dropped on a piece of lint, applied to the skin, and covered with a watch-glass, very soon causes redness and rapid vesication in most persons. This is a good way of raising a blister when it is desired to apply powdered morphia endermically to relieve severe pain.

The application of blisters should not be made directly over an inflamed part. There is some evidence to show that a strong stimulus applied very near an inflamed organ may increase the paralytic dilatation of its capillaries, and so add to the disease. Blisters should not be applied where the skin is loose, nor over any prominence of bone, nor to the breast during pregnancy. It should moreover be borne in mind that the cantharidine of a blister may be absorbed by the skin, and act on the kidneys, producing strangury and bloody urine. This accident may be obviated by sprinkling powdered camphor over the blister before placing it on the skin, or a thin piece of silver paper may be interposed. In persons of feeble vitality, a blister left on too long time has been known to induce dangerous sloughing.

When vesication is specially desired, there is no need to leave the blister on for twelve hours or more, for it may be removed at the end of six or eight hours, and a warm linseed poultice applied. If the blister be opened, which is best done by pricking the most dependent part with a needle, sweet oil and cotton wool is the best dressing. The practice of maintaining a blister as a running sore or *eczema*, by applying irritating ointments, is not often resorted to now. The process causes great pain and exhaustion of the system, and is one rather of depletion than of counter-irritation. In the case of children, blisters should be used with caution, being kept on till the skin is well reddened, when they should be replaced by a poultice. It is also a good plan not to open the blister, as the effused serum forms the best dressing for the excoriated surface, and by following this plan the child is saved much worry and pain.

Uses.—In its primary action a blister acts as a local stimulant, but when it remains on long enough to produce extensive vesication and discharge of serum, it acts as a depletive and depressing agent. This primary and secondary action of blisters has been much insisted on by the late Dr. Graves of Dublin, who found great benefit in cases of fever with apathy and prostration from the application of *flying blisters* to various parts of the surface. Thus a blister over the præcordial region, kept on for about one hour, and then removed, was observed to rouse and stimulate a flagging heart. In other cases the flying blister might be placed at the chest or back, or else behind the head on the neck. Care should be taken not to leave the blister on long enough to cause vesication, and the size of the blister should be fairly large.

Vesication by a blister is of service in many brain-affections attended with congestion and tendency to serous effusion, such as in the chronic stages of hydrocephalus, and non-tubercular

meningitis. In hysterical paralysis narrow strips of blister placed completely round the affected limb have proved curative. A strip round the throat may cure nervous aphonia. A strip of blister one inch wide will sometimes stay the spread of erysipelas along a surface. In cases of pleuritic or pericarditic effusion the repeated application of blisters to the chest-wall is of manifest advantage. In effusions into joints (hydrarthrosis) blisters aid absorption; and it has seemed to the writer that absorbent remedies, such as iodide of potassium, often begin to do good as soon as a blister appears to have once set the absorptive process in action. In the joint-affections of acute rheumatism, 'the blister treatment' has attracted notice. Armlets and wristlets of blister-plaster are applied close to the inflamed joints during the fever, and the serous discharge from the blister is kept up by means of linseed-meal poultices.

In the obstinate acid vomiting of gouty patients, a blister over the epigastrium often gives relief. Some forms of neuralgia, as for example pleurodynia, may yield to a blister over the seat of the pain. At times obstinate pleurodynia, or mastodynia, can be relieved by flying blisters applied in the vertebral groove on the affected side, where a tender spot can often be detected on pressure. Blisters should be avoided in cases of renal and vesical inflammation, as the absorption of the cantharidine may increase the mischief.

Counter-irritation by heat.—The skin can be rapidly blistered by applying a hammer or a small flat iron heated in a spirit-lamp or boiling water. The skin is tapped for a few seconds with the hammer, just to induce redness of the part. In some forms of rheumatism, neuralgia, and spinal weakness, this practice has been followed by satisfactory results. Vesication of the skin by the *ferrum candens*, or hot iron, has been used in chronic joint-disease.

Moxas are used for the purpose of causing severe counter-irritation. European moxas are made either with cotton wool soaked in solution of nitrate of potash, or of the pith of the sunflower, which naturally contains this salt. A wet rag is placed on the skin; in the centre of this is a hole in which the lighted moxa is placed, which gradually burns down to the skin and produces an eschar which in due time separates by suppuration. In spinal affections, and in some forms of paralysis of the sensory and motor nerves, moxas are said to have done good; but their application is very painful and now they are seldom employed.

Pustulants.—**Action.**—The agents belonging to this class of counter-irritants produce a pustular eruption on the part of the skin to which they are applied.

Enumeration and Application.—Among pustulants may be placed croton oil, tartarated antimony, and strong solution of nitrate of silver. When croton oil is applied to the skin, it acts as an intense irritant, producing an eruption which is at first papular but very soon becomes pustular. Tartarated antimony in the form of ointment, or in hot aqueous solution, is a powerful counter irritant, producing pustules which resemble those of variola. When applied thus it may, by becoming absorbed, induce symptoms of

gastro-enteritis. It should not be applied to parts usually uncovered, as the pustules leave marks behind them; and under all circumstances the remedy, being a painful one, must be used with caution. Strong solution of nitrate of silver will produce pustulation, but it is seldom employed for this purpose.

Issues have long been used as counter-irritants. An issue is formed by placing on the skin a piece of adhesive plaster, in a hole in the centre of which a fragment of caustic potash is inserted. The caustic causes an eschar, and when this has come away an issue-poea is placed in the cavity left by the eschar; this poea acts as a foreign body, and keeps up suppuration. One drachm of pus may be discharged daily by an issue; more than this is too great a drain on the system. An issue requires to be dressed daily, and when it has been long open and running it must not be healed too suddenly. Issues over the spine have been found useful in chronic spinal disease; and in some chronic brain-affections, with hyperemia and congestive tendency, an issue in the back of the neck or in the arm is frequently of service.

Setons.—A seton is made by passing a narrow-bladed knife under a fold of skin and then carrying a few silk threads through the incision by means of a probe or long needle. The threads remaining in the wound prevent it from healing, and maintain a free purulent discharge. Setons are used for the same purposes as issues, and they have proved useful in certain intractable forms of headache—the seton being inserted in the skin of the neck. Setons have been used in cases of cystic bronchocele with thickened walls; in chronic inflammation of the bladder; in many chronic affections of the uterus; in various chronic skin-diseases of an obstinate character; in chronic inflammations of the eye, and ulcerations of the cornea; and in the early stages of pulmonary phthisis.

In acute affections issues and setons are never employed, and they should not be placed over any part where there is much movement, as a troublesome sore may be the result. It is necessary to bear in mind that issues, setons, and pustulants are, like blisters, when kept on long enough to induce serous discharge, of the nature of evacuants. They carry off nutrient material from the blood, and therefore are more or less depressing and exhausting to the system, and their repeated or protracted employment will tend to induce the irritative fever of debility.

COUP DE SOLEIL (Fr).—A synonym for sunstroke. *See* SUNSTROKE.

COW-POX. *See* VACCINIA.

COXALGIA (*coxa*, the hip, and *algos*, pain).—Pain in the hip-joint. *See* JOINTS, Diseases of.

CRACKED-METAL or **CRACKED-POT SOUND** (*Bruit de pot fêlé*). A peculiar sound elicited by percussion, and resembling that emitted on striking a broken jar or a metallic vessel. *See* PHYSICAL EXAMINATION.

CRAMP.—This name is applied to certain painful varieties of tonic spasm. In its most

familiar form it affects the calves of the legs coming on principally at night, on the occasion of some slight movement of these parts. The affected muscles, mostly on one side, contract with such energy as to give rise to a board-like rigidity, together with sensations of an agonising character. The attack rarely lasts more than a minute or two, though it may more or less speedily recur. It is perhaps best cut short by a vigorous but steady voluntary contraction of the opposing extensor muscles of the foot. Where it is more obstinate than usual firm pressure around the thigh or upon the great sciatic nerve, sometimes gives relief. Cramp is often associated with some irritation of the stomach or of the intestines, especially in children or delicate nervous persons. In this way it is produced not infrequently when arsenic in medicinal doses has been continued for some time, and is beginning to exert a slightly poisonous effect upon the system. In a more general form it often occurs, to a marked extent, in cholera. Other forms of painful spasm are by no means common, if we except colic. *See* also SPASM.

H. CHARLTON BASTIAN.

CRANIOTABES.—*See* SKULL, Diseases of.

CREPITANT (*crepito*, I make a noise).—When applied to a body, this word signifies that it is capable of yielding the sensation or sound of crepitation. It is also associated with a râle, to indicate a peculiar character which it possesses. *See* PHYSICAL EXAMINATION.

CREPITATION (*crepito*, I make a noise).—A sensation or sound of crackling. It may be observed in morbid states of the bones, joints, or subcutaneous tissue; but the term is more frequently applied to a physical sign connected with the lungs. *See* PHYSICAL EXAMINATION.

CRETINISM (*cretin*, chalk)—*SYNON.*: Lat. *Cretinismus*; Fr. *Crétinisme*; Ger. *Cretinismus*; Ital. *Cretinismo*.

DEFINITION.—A condition of idiocy arising from endemic causes, associated with imperfect development and deformity of the whole body, varying however in degree.

This condition of physical and mental degeneracy is not limited to any nationality. It obtains in the great mountain-chains of Europe, Asia, and America. In Europe it is met with in the valleys of Switzerland, Savoy, and Piedmont; and it abounds in the neighbourhood of Salzburg, Styria, and the Tyrol. It is less frequently met with in the Pyrenees and in the valleys of the Auvergne in France. Even in England it has been met with in various parts, among others in the dales between Lancashire and Yorkshire. Although more frequently met with in valleys, it is not unknown on plains which are subject to inundations.

DESCRIPTION.—The degrees of cretinism are numerous. A residence in one of the valleys where this affection exists, enables one to trace the various steps of degeneracy, commencing with those who are taking part in the industrial life of the valley, down to the helpless individuals who are leading only a vegetative existence.

The typical cretin presents a marked physical

conformation. He is stunted in growth, rarely reaching five feet in height. His skin is of a tawny yellowish hue, thickened and wrinkled; and looks as if too large for the body. There is also a great increase of subcutaneous areolar tissue. His tongue, large and thick, with hypertrophied papillae, always displays lessened power of co-ordination; and often hangs from the mouth. The mouth is partly open, margined by thick fissured lips, and with the saliva running over the chin. The face is large; the lower jaw is drooping, and its angle obtuse. The eyes are often affected by strabismus, obliquely placed, and small; and the lids are commonly puffy. The belly is pendulous from the laxness of the skin. The lower limbs are generally short and deformed, and the gait is waddling. The head is deformed, the forehead retreating, the top flat, and the occipital region ill-developed. The cranium is brachycephalic. The nose is broad and flattened. Puberty is often delayed to the twentieth year. The mammae in the female are large and pendulous, the same remark applies to the genitals in the male. The intellectual faculties are imperfectly developed. The cretin is often unable to speak, and his hearing is frequently defective. The affection is usually associated with more or less enlargement of the thyroid gland. His viability is low, few living beyond thirty years of age. The sexual functions are abnormal, masturbation is frequent; and the subjects of cretinism are often impotent.

ÆTIOLOGY.—The conditions for the development of cretinism are hereditary predisposition; the action of deteriorating influences on the parents, such as unwholesome dwellings and non-nutritious diet; and accidental causes operating on the infant during the period when its physical and intellectual life are developing. The last-named causes are atmospheric and possibly geological conditions, peculiar to special localities. Humidity of the soil and air in valleys where there is little interchange of the atmosphere, and the existence of magnesian limestone in the soil, are probably the most potent factors. Cretinism is not met with as an endemic disease on elevated plateaux, nor in cold countries where sudden changes of temperature are uncommon. Goitre is a frequent accompaniment of cretinism, and would appear to be developed under the same conditions. The cases of cretinism met with in England present features which are indicative of a scrofulous origin. There is a condition of idiocy associated with arrest of growth and development at the period of first dentition, not unfrequently met with in England, which has been termed *Sporadic Cretinism*. Some of these cases have been traced to alcoholism on the part of the progenitors, and are usually associated with an absence or atrophy of the thyroid body. There is reason to believe that children become cretinoid when taken to reside, at the period of their early development, in localities where the disease is markedly endemic. There are numerous, well-attested instances of healthy women living during their pregnancy in cretinic districts bringing forth cretinoid children, who removing from such localities, propagate healthy children. By far, however, the greater number of cretins arrive at their helpless condition by successive

steps of degeneracy in their ancestors. It has been thought that cretinism was due to premature ossification of the cranial sutures, especially of the spheno-basilar suture; and that this was caused by drinking water largely charged with lime. It is impossible, however, to regard this premature ossification when it does occur, as other than one of the outcomes of the malady and not its cause. Moreover there are numerous examples where the synostosis is deferred instead of being premature.

ANATOMICAL CHARACTERS.—Pathological anatomy shows that the bones of the cranial vault are thickened and without diploë. The basilar groove is generally wanting. The foramina for the passage of arteries and nerves are somewhat smaller than natural. The occipital fossae are flatter than usual, as if the flattening had resulted from a compression of the cranium from above downwards. Every variety of deformity of the cranium is met with of the brachycephalic type. The brain is usually small, asymmetrical, pale, and infiltrated with serum. Premature synostosis is occasionally met with at the spheno-basilar suture, and with it a rectangular form of the base of the skull this, however, cannot be regarded as a constant condition.

DIAGNOSIS.—The diagnosis of cretinism may be made in childhood, from the slowness of the development of the body, the stupid expression, the postponement in the evolution of the teeth, and of the ossification of the fontanelles and sutures, the tawny yellow colour of the skin, the thick and goitrous neck, the slaving, and the delay of speech and of walking.

TREATMENT.—This consists in removing the child as early as possible from the circumstances which have produced the disease. He should be taken to a locality where the soil is dry and porous, and should have frequent baths with friction to the surface of the body. The diet should be of the most nutritious kind—a diet into which animal food largely enters. The administration of cod-liver oil and of the lacto-phosphate of lime and iron is indicated. Early education should be commenced as to habits of cleanliness, followed by systematic physical exercise of the various muscles. All intellectual advancement must be sought for through the improvement in every way of his physical condition. The lower animal life may thus be supplemented, if earnest efforts are used, by increased capacity for rational enjoyment, and a more or less useful existence.

J. LANGDON DOWN.

CRIMINAL IRRESPONSIBILITY.

HISTORICAL SUMMARY.—A medical opinion as to the condition of an accused person is often necessary in order to determine whether he or she can be held accountable for criminal acts. Such an opinion generally depends on the presence or absence of insanity, or on the connection which may be traced between this mental condition and the act in question. In the article on Legal Insanity it is explained that it is only within a comparatively recent period that insanity has been admitted as an excuse for crime, except in those comparatively rare cases, in which, as Justice Tracey expressed it in 1733, 'a person does not know what he is doing, or

more than an infant, a brute, or a wild beast.' See *INSANITY, LEGAL*. This view fairly represents the state of public and of legal opinion until the latter years of the eighteenth century. The subsequent enlightenment of the public mind did not receive juristic expression until the trial of Hadfield in 1800, when Erskine first enunciated the doctrine, that 'delusion where there is no frenzy or raving madness is the true character' of such insanity as implies irresponsibility. The most important case in the history of this question was that of Bellingham, who was executed in 1812 for shooting Mr. Spencer Perceval. In this case Lord Chief Justice Mansfield said, that if a person labouring under mental derangement were capable in other respects of distinguishing right from wrong, 'he could not be excused for any act of atrocity which he might commit.' 'It must be proved beyond all doubt,' he added, 'that at the time he committed the atrocious act he did not consider that murder was a crime against the laws of God and nature.' The trial of MacNaughton in 1843 for the murder of Mr. Drummond led to the most authoritative statement of the law which has ever been obtained in this country. MacNaughton was acquitted on Chief Justice Tindal's direction that the point for the jury to consider was whether 'at the time the act was committed' the accused 'had that competent use of his understanding as that he knew that he was doing by the very act itself a wicked and a wrong thing.' The general application of this doctrine would have greatly enlarged the area of irresponsibility, and its enunciation at that time produced considerable surprise and even consternation. The matter was indeed regarded as so urgent that the House of Lords immediately ordered a series of questions to be laid before the fifteen judges with the view of settling the state of the law. In the answers to these questions it was in substance laid down, that to entitle an accused party to acquittal on the ground of insanity it is necessary that he be of diseased mind, and at the time he committed the act not conscious of right or wrong; or, that he be under some delusion which made him regard the act as right. But this statement has been far from effecting a final settlement of the question.

Most writers on medical jurisprudence have insisted that the real criterion of responsibility is the freedom of the will, or the power of the individual to control his actions. This has been more or less advocated by Esquirol, Marc, Ray, Pagan, Jamieson, Mittermaier, and Von Krufft-Ebing. Esquirol dwells strongly on the importance of the freedom of the will. Ray includes it in the comprehensive statement which has received the approval of so many medical jurists. 'Liberty of will and action,' he says, 'is absolutely essential to criminal responsibility, unless the constraint upon either is the natural and well-known result of immoral or illegal conduct. Culpability supposes not only a clear perception of the consequences of criminal acts, but the liberty unembarrassed by disease of the active powers which nature has given us, of pursuing that course which is the result of the free choice of the intellectual faculties.' Pagan observes

that the 'loss of control over our actions, which insanity implies, is that which renders the act which are committed during its continuance undeserving of punishment.' Jamieson puts the question. 'Had the lunatic at the time of committing the deed a knowledge that it was criminal, and such a control over his actions as ought, if it existed, to have hindered him from committing it.' Dr. Taylor says: 'The power which is most manifestly deficient in the insane is generally the controlling power of the will'; and he expresses the opinion that 'we have here a fair criterion on which responsibility or irresponsibility may be tested.' Dr. Bucknill's view is substantially the same. 'Responsibility,' he says, 'depends upon power, not upon knowledge, still less upon feeling. A man is responsible to do that which he can do, not that which he feels or knows it right to do. If a man is reduced under thralldom to passion by disease of the brain he loses moral freedom and responsibility, although his knowledge of right and wrong may remain intact.' The latest German code puts responsibility upon the same basis. 'An act is not punishable,' according to it, 'when the person at the time of doing it was in a state of unconsciousness; or of disease of the mind, whereby free volition was prevented.' Mittermaier and Von Krufft-Ebing sanction the attempt to render the meaning of 'free volition' more definite by describing it as made up of *libertas judicii* and *libertas omittii*, freedom of judgment and freedom of choice. Casper somewhat obscurely defines criminal responsibility as 'the psychological possibility of the efficacy of the penal code.' Mr. Balfour Browne, a recent writer, gives as the best definition 'a knowledge that certain acts are permitted by law, and that certain acts are contrary to law, and, combined with this knowledge, the power to appreciate and be moved by the ordinary motives which influence the actions of mankind.' Dr. Guy thinks that every person who is insane must be regarded as wholly irresponsible, and that the law of England ought to be assimilated to that of France in the declaration that: 'Il n'y a ni crime ni délit lorsque le prévenu était en état de démence au temps de l'action.' Mr. Warren, on the other hand, suggests that a person should not be held irresponsible unless he were as 'unconscious of his act as a baby.' Dr. Maudsley and others hold that the determination of responsibility in cases where insanity is alleged depends on whether a connection can or cannot be traced between existing disease and the act.

Insanity has been pleaded as an excuse for acts of theft; but such cases are rare, and never occur except where the social position of the accused adds importance to the decision. Indeed it may almost be said that the plea is never raised, except in order to avoid capital punishment. Hence it is, that in the discussions which have arisen the question has been intimately associated with the law of murder and homicide. A special inquiry into the state of this law by a committee of the House of Commons¹ has consequently given occasion to the enunciation of important views as to the legal relations of insanity

¹ Report of Select Committee of the House of Commons on the Homicide Law Amendment Bill, July 21, 1874.

and responsibility. Evidence was furnished to the Committee by Lord Chief Justice Cockburn, Baron Bramwell, Mr. Justice (now Lord) Blackburn, and Sir James Fitz-James Stephen. The immediate object of the Committee was to examine a bill drawn by Sir James Stephen for the codification of the law of homicide. In the clause of the bill which deals with the relations of disease and responsibility, homicide is stated to be 'not criminal if the person by whom it is committed is at the time when he commits it prevented by any disease affecting his mind—(a) from knowing the nature of the act done by him, (b) from knowing that it is forbidden by law, (c) from knowing that it is morally wrong, or (d) from controlling his own conduct.' But it is stated to be 'criminal, although the mind of the person committing it is affected by disease, if such disease does not in fact produce one of the effects aforesaid in reference to the act by which death is caused, or if the inability to control his conduct is not produced exclusively by such disease.' It was, however, proposed in the bill that, 'if a person is proved to have been labouring under any insane delusion at the time when he committed the homicide, it shall be presumed, unless the contrary appears or is proved, that he did not possess the degree of knowledge or self-control hereinbefore specified.' That is to say, where delusion exists, the burden of proving moral capacity would be shifted, the prosecutor having to prove its existence, instead of the accused having to prove its absence. The opinions elicited during the enquiry showed that the law is regarded by legal authorities as being at present too uncertain in its operation, and as failing to recognise some of the most important elements in the question. The divergent character of the recommendations which were made showed, however, that legal opinion is much divided not only as to the proper relations of insanity and crime, but also as to the essential elements of responsibility. In the meantime, therefore, the statements of the fifteen judges after the MacNaughton case remain the chief exposition of the English law where insanity is pleaded in excuse for crime.

Present state of the question.—It is necessary, in order to justly appreciate the present aspect of the subject, thus to trace its more recent history, and it would be useful, did space permit, to present an estimate of the comparative value of the several tests or criteria which have been proposed for the determination of cases in which insanity has been alleged. These criteria may be broadly summarised in the following six propositions. According to one view a person should be held irresponsible for an act if at the time of committing it (1) he laboured under insanity of any kind or degree; according to another, if (2) he laboured under delusion; or (3) if he was ignorant of right and wrong; or (4) had not power to appreciate and be moved by ordinary motives; or (5) had lost the controlling power of the will; or (6) if the act is traceable to, or its nature has been determined by mental disease affecting the agent. The last of these views is the only one to which fatal objection may not be raised both on the theoretical and practical sides. The

others are all too vague to be of much advantage; and they rather tend to introduce new difficulties than to remove those already existing. The proposition therefore which seems to approach nearest to a solution of the difficulty is that irresponsibility must be admitted whenever the act is traceable to, or its nature is determined by mental disease affecting the agent. It will of course be understood that under such a rule the term 'mental disease' must be held to include both congenital and acquired disorders: arrest of development being as much a morbid condition as functional or structural change. This view of the subject may not be ultimately accepted in the precise terms of the proposition here given; but the principle on which it rests seems to afford the only safe basis upon which we can go. As has already been shown, it has not hitherto been regarded in this light by the majority of the judges; but there have been indications of late years that judicial views are tending in that direction. The late Lord Wensleydale and others have given sanction to the principle in their judicial statements. And the present Lord Justice-General of Scotland (Ingis) gave definite expression to it in one case (*Brown*, Sept. 1866). He told the jury that the main question was 'whether the prisoner was in such a state of insanity at the time, as not to be responsible for the act which he had committed', and in order to constitute such insanity he said that 'it must be clearly made out that at the time of committing the act the prisoner was labouring under mental disease in the proper sense of the term, and that that mental disease was the cause of the act.' In America the doctrine has been frequently acknowledged, but never more fully and tersely than by Judge Doe, of New Hampshire (*State v. Pike*), who comprehensively defined the medical relations of both criminal irresponsibility and civil incapacity, when he stated that 'a product of mental disease is neither a contract, a will, nor a crime.' One important point is to prevent persons from being punished for actions which are the direct outcome of pathological processes. But it is of equal importance to avoid the adoption of a principle which would make the existence of slight mental irregularities incompatible with responsibility. There does not appear to be any danger of this in acting on the principle which is here enunciated. For it lies in the very nature of the cases in which the doctrine could be applied, that the condition to which it is proposed that irresponsibility should be attached must be one which is known to exhibit itself in acts of serious and even criminal character. If the trained observer of disease is able to recognise in an act—which is ordinarily followed by severe punishment—a direct result or a characteristic feature of a morbid process, of the existence of which there may otherwise be sufficient proof, the question of responsibility cannot present any serious difficulty. It may admit of doubt whether a person is responsible for not controlling his actions, or for not knowing right from wrong, or even in some cases for the harbouring of a delusion. But once let it be proved that an act is the natural result of a disease under which a person is known to labour, and the question must be

practically removed from the field of discussion. Before, however, the principle can be accepted as fully satisfactory, it is necessary to enquire whether its application would permit insane persons to be held responsible who ought not to be so considered. In other words, are there states of insanity in which a person is irresponsible for acts to which he has not been predisposed or impelled by the insanity? It is perhaps impossible to give such an answer to this question as would be both definite and complete; but for practical purposes we think it may be answered in the negative. Where the insanity is of such a nature that it does not modify the whole conduct, we believe it will be found in practice necessary to admit the existence of responsibility for acts where there is no demonstrable connection between them and the mental disease. The insane persons who on this principle might be held responsible, would be found solely among those whose irresponsibility could only be admitted after very searching enquiry, and whose insanity was of that kind and degree which has often been declared by medical writers to be consistent with responsibility. It is not to be supposed that under this rule difficulties would cease. It would often be hard to show in cases of actual disease that there was good reason for believing in its existence, or that it was really contributory to the act committed. This, however, would not result from any defect in the principle, but from that imperfection of our knowledge which renders the perfect application of any principle impossible. Let the task of the medical witness be limited to the demonstration of facts indicative of disease and its consequences, and he will at least be acting quite within his special province and might expect that reasonable weight would be attached to his opinion. And if juries were instructed that the law does not hold a person responsible for acts committed under the influence of disease, it is scarcely conceivable that anyone would be found guilty where good cause had been shown even for the reasonable supposition of such an influence. Whatever may be the view ultimately adopted, it would seem to be in every way desirable that the attention of the medical expert should be confined to the elucidation of the medical facts, and that he should not be required to deal with questions which are legal and abstract, and in no way specially medical. The condition known as *diminished responsibility* has not been alluded to in this article. It is only indirectly recognised by British law, and therefore, though much is to be said in favour of its recognition, it is unnecessary to deal with the subject here.

JOHN SIBBALD.

CRISIS (*eplois*, a decision, a turn).—Crisis is a term applied to the rapid deferescence of an acute febrile disease. It has wandered somewhat from its original meaning, which was 'judgment,'—primarily an operation in the mind of the observer, but reflected upon the phenomena observed. The converse term, employed to designate a gradual subsidence of fever, is *lysis*.

Crisis formed at one time the basis of an important medical doctrine. Certain days from the onset of the disease on which the crisis com-

monly occurred were considered to be propitious. The seventh day was especially favourable, while the sixth was the most unfavourable; speaking generally, the odd numbers or the multiples of 7 were propitious, and even numbers and such odd numbers as stood near multiples of 7, such as 19, were unpropitious. The preparation also for a crisis was indicated and the critical day foretold by remissions perceptible some days previously. The whole morbid process of fever was represented as a process of elaboration by which a *materia morbi* was prepared for expulsion, and an essential feature of the crisis was a critical evacuation, by means of which this was eliminated.

The doctrine of crisis and even of critical days was not pure imagination or superstition, but was founded originally on careful observation. In times when nothing was known of the organic lesions which give rise to fever, and in countries where a large proportion of the diseases were of a malarious origin, it would afford data for prognosis and conduce to appropriate treatment; and at the present day in hot climates a crisis is anxiously looked for in febrile attacks on a given day, and, as is well known, a critical fall of temperature and improvement in the general symptoms precede in pneumonia improvement in the physical signs.

In order to constitute a true crisis the deferescence should occupy less than forty-eight hours, and it often takes place in a much shorter time. The fall of temperature should be accompanied by a corresponding reduction in the frequency of the pulse, and should coincide with a feeling of relief and a return of strength; the skin will be warm and soft, the tongue moist, and there will be indications of reviving appetite; there may or may not be a critical evacuation, but the secretions will become more natural in amount and character.

This favourable mode of termination of an acute febrile disease is more common than is usually supposed. The circumstances under which it is most likely to occur are when the attack begins abruptly and the temperature rises rapidly, the natural course of the disease being short and not attended with organic lesions, such as will of themselves keep up fever. After twenty-one days, termination by crisis is not to be expected. The more marked the onset, as, for example, by a definite rigor, the more rapid the rise of temperature and the greater the height to which it reaches, the greater the probability of an early critical termination.

OCCURRENCE.—The diseases in which the conditions favouring a crisis are realised, and in which this mode of termination is observed, belong to various classes.

Among the *specific fevers*, eruptive and continued, it occurs frequently in variola, but in severe cases it is interfered with by the febrile disturbance excited by the eruption. In measles it is very common: in scarlet-fever a true crisis is seen only in mild cases, though the onset of this disease is peculiarly abrupt. The mode of termination of typhus is essentially critical, but as a rule the crisis is not sharp. Relapsing fever affords the best examples of crisis, which is moreover attended by a critical evacuation in

the form of profuse perspiration, the temperature sometimes falling 10° F. in as many hours, and the patient passing from a state of extreme suffering and oppression to almost perfect ease and comfort. In enteric fever *lysis* is the mode of termination.

Remittent fevers often present crises, which may be true and curative, or false and illusive; and the sun-fever and common continued fever of hot climates, and tropical diseases generally, have a tendency to fever running high very early and breaking abruptly at a critical period.

In this country *feverish colds*, attacking the throat or taking the form of influenza or catarrh, often terminate critically in three or four days. Erysipelas may so end, but at a later and less definite period. The sharp *febrile attacks* which sometimes occur *after childbirth* often exhibit a very decided crisis. In *pneumonia* the natural termination is by a well-marked crisis, which may take place as early as the fifth day, or be deferred to the ninth, after which a critical termination is not to be expected, and the suspicion may be entertained that the case is not one of frank pneumonia, the prognosis becoming grave. As has been already stated, the general improvement precedes the indications by physical signs of resolution in the inflamed lung. Pleurisy is said also to terminate critically, but it is not in the same definite way as pneumonia.

The *critical evacuations* which entered into the original notion of a crisis are really a common attendant. The most common is a profuse warm perspiration, which may occur whatever the disease may be. Occasionally the evacuation is a copious flow of urine, or it may take the form of diarrhoea. Epistaxis or hæmorrhoidal flux is a more rare and doubtful critical evacuation. A common critical phenomenon is a prolonged, sound, and refreshing sleep.

The question whether or not a favourable crisis affects the odd rather than the even days has been a frequent subject of dispute, and it still remains undecided. It is not, however, of any importance; but another point handed down with the doctrine is worthy of attention, namely, that indications of an approaching crisis are often given two or three days beforehand in slight remissions of fever. By the presence or absence of such remissions at a certain period of the attack, or by a continuous rise of temperature where a remission might be expected, important prognostic information may be afforded and indications for treatment obtained.

THERAPEUTIC INDICATIONS.—The main therapeutic deduction from a study of crisis as a termination of acute disease is, that we should not hastily interfere with the reactions by which the system adjusts itself to altered conditions or meets the incidence of the causes of such disease, but contribute to their completion. We do not assume the existence of a *vis medicatrix* tending invariably to the restoration of health; but we must recognise the power inherent in a living organism to respond by internal changes to external influences, and to regain the balance when this has been disturbed. In this process a certain cycle of changes must be gone through, and the great opportunity for treatment of an

active kind, should any be required, arises when the course, direction, and probable duration of these changes are known, and when agencies can be brought to bear at a given moment, which will contribute to bring about the appropriate critical evacuation or a critical sleep, through which a return to a normal condition would naturally be effected.

WILLIAM H. BROADBENT.

CRITICAL.—Having relation to a crisis. *See* CRISIS.

CROUP.—**DEFINITION.**—Croup is a word which, in accordance with its etymology, originally meant *stridulous breathing*, a symptom, therefore, of laryngitis stridulosa, laryngismus stridulus, oedema of the glottis, laryngo-tracheal diphtheria, and other affections which permanently or spasmodically contract the chink of the glottis. It was imported from the Scottish vernacular into medical nomenclature by Dr. Francis Home, of Edinburgh, in 1765, when he published a tract of 60 sparsely printed pages, entitled *An Inquiry into the Nature, Cause, and Cure of the Croup*. It has since drifted into very strange and very different meanings. 'In France,' to quote the Dictionary of Littre and Robin, 'it is a term now generally reserved for *tracheal diphtheria*;' in Germany, it is applied to *membranous deposits on the internal surface of organs*, such expressions as 'croup of the uterus' and 'croup of the intestine' being in current use; in Great Britain it is used, as employed by Home, Cheyne, and their followers, to designate a disease which they believe to be distinctive and separate, but which is declared by an increasing number of British physicians, the followers of Bretonneau, to be a mere literary composite of diseases pathologically different from one another. In a general way, the question—What is croup?—has now been answered. It is necessary, however, still further to explain the position which 'croup' at present holds in the literature and science of British medicine.

In 1826 Bretonneau of Tours, by the publication of his work entitled *Recherches sur l'Inflammation Spéciale du Tissu Muqueux, en particulier sur la Diphthérie*, created the name, and first pointed out, in that and subsequent writings, the true pathology of diphtheria. He did not, however, describe a new disease. He only disentangled it from other diseases in which it had been mixed up in description. Modern literary research has shown that diphtheria has at intervals prevailed, under various names, in many countries, from the earliest medico-historical times. Home, in his little monograph, describes only eight cases; and of these, all of which he calls by the name of 'croup,' five are manifestly tracheal diphtheria, and three are cases of laryngitis. As no false membrane was seen in the three cases of laryngitis, he concluded that it had been absorbed, or that the treatment had prevented its formation! For a long period his successors, British and foreign, continued to make similar mistakes; and indeed till Bretonneau published the result of his clinical study, the error now adverted to was universally accepted as the truth. In 1801, Dr. John Cheyne of Edinburgh published his *Essay on Cynanche*

Tracheitis, or Croup, a pamphlet of 80 pages illustrated by five excellent plates, the work of the illustrious Charles Bell. Cheyne, like Home, has confounded together infantile laryngitis and infantile tracheal diphtheria in one disease, which he calls 'cynanche trachealis or croup.' He attributes the recoveries from the former to the energy of the bleeding and purging; and the deaths from the latter to the imperfect adoption of that treatment. Dr. Cheyne's essay contains only ten cases. In the history of the five which terminated in recovery, nothing is said of false-membranes having been seen, and in four of the five which terminated in death, there was found false-membrane, which is well depicted by Charles Bell in the coloured plates. If the account now given of the constantly quoted, and often misquoted, little tract be correct, where is the foundation for the statement reiterated up to the hour at which we write by a succession of British authors, that the said writings of Home and Cheyne contain the description of an individual disease—croup—possessing essentially different features from the laryngeal and tracheal diphtheria of Bretonneau?

It must be admitted that, while the inference to which the preceding remarks are intended to lead is in accordance with the views of some eminent British physicians, it is at variance with the teaching of others who claim respectful attention. Dr. Charles West, in the edition of his *Lectures on the Diseases of Infancy and Childhood*, published in 1874, when discussing 'Diphtheria or Angina Maligna,' says:—'I have come to the conclusion which I long hesitated to adopt, that what differences soever exist between croup and diphtheria, they must be sought elsewhere than in the pathological changes observable in the respiratory organs. The mere extent of false-membrane in the air-passages certainly affords no ground for a distinction between the two affections, though I think it is more common to find the false-membrane reaching to the tertiary bronchi in diphtheria than in primary croup.' In these sentences he intimates his belief in a non-diphtheritic membranous croup—a disease which many maintain has no existence, except in books. In the same work, in the lecture on croup, he says:—'It can scarcely be necessary to tell any of you that *croup* is the English name for the disease designated by scientific writers *cynanche trachealis* or *cynanche laryngea*. It consists in inflammation, generally of a highly acute character, of the trachea or larynx, or both, which terminates in the majority of cases in the exudation of false-membrane, more or less abundantly, upon the affected surface.'—(Lecture xxiii. p. 390, 6th edition, London, 1874.) The only case of croup given by Dr. West in the lecture is one which, if Bretonneau's teaching be correct, is a typical case of diphtheria affecting the air-passages. The case and the sentences by which it is introduced, are subjoined:—

'The danger,' says Dr. West, 'of being lulled into security by the apparent improvement of a child who has been attacked by croup, is so serious that before proceeding to consider the treatment of the disease, I will relate to you a case by way of caution. On June 26, a little girl, four years old became hoarse and lost her appetite, though

she did not appear otherwise ill. On the 27th, she seemed less well, and in the night was very restless, and had difficulty of breathing. On the 28th, respiration was more difficult, and though she had but little cough, she seemed sometimes in danger of choking. In the night a croupy sound accompanied her breathing, and violent attacks of dyspnoea were of frequent occurrence. On the 29th, she was taken to a surgeon, who gave her some medicine, after each dose of which she was sick; and this sickness was followed by much relief, and by an almost complete cessation of the croupy sound. This improvement was thought to have continued during the 30th; the child slept quietly during the night, and was considered so much better by her parents that she was brought by them to the Children's Hospital at 9 a.m. on July 1. As she lay in the lap in a sitting position, her countenance was pale and livid, her respiration was sibilant, her surface cool, her pulse very frequent and feeble; but she did not appear to be in any of the distress usual in the advanced stages of croup. At 9 a.m. she was admitted, at 6 p.m. she died, though no great distress nor violent struggle for breath preceded her death. The extensive deposit of false-membrane in the trachea and bronchi showed that in spite of her apparent amendment for a season, disease must all the time have been advancing, unsuspected by her friends, overlooked even by her medical attendants.'

This case, given by Dr. West as a case of the disease which he calls croup in *contradistinction to diphtheria*, will be regarded by the medical profession in France, and by all other followers of Bretonneau, as a typical and graphically described example of diphtheria implicating the air-passages. They will say that it was typical in its manner of invasion in its course and duration, in its being relieved by emetics, in the anaesthesia and asphyxia proclaimed by quietude and the pale lividity of countenance observed nine hours before death; and finally, that it was typical in the extensive deposit of false-membrane in the trachea and bronchi.

In illustration of the remarks made at the beginning of this article on the meanings of the term *croup*, it is well to remind the reader that Dr. West's case, now quoted, will be called *croup* by French physicians, for they reserve that name for the manifestation of diphtheria in the air-passages.

ÆTIOLOGY.—The disease which Home, Cheyne, West, Sanson, and many other older and recent British authors of repute call *croup*, is an acute inflammation of the larynx or trachea, or of both, which, when it runs its natural course, generally, they say, terminates in membranous exudation on the inflamed mucous surface. The affection which Bretonneau, Tronseau, Peter, Barthéz, Sanné, and the entire modern school of French physicians, call *croup*, is the membranous manifestation in the larynx and trachea, or in both, of diphtheria, a general asthenic disease. The French physicians, with whom agree George Johnson, Semple, and other British physicians, including the writer, hold that membranous exudation is never a result of simple acute inflammation, or, in other words, that there is no such disease as the croup of Home, Cheyne, West, and

ransom, these authors having blended two essentially different diseases in one description.

No statement could have been written intelligibly in respect to the etiology of 'croup,' without these prefatory remarks. The subject now admits of being very briefly disposed of. Diphtheritic croup, that is to say, the croup of French authors, is considered in the article *DIPHTHERIA*. The common exciting causes of inflammations of the larynx and trachea are exposure to chilly winds and cold damp air; and the sudden transitions from mild to cold wet weather. Cold wet places are those in which inflammations of the larynx, trachea, bronchi, and pulmonary parenchyma are most prevalent. The much greater frequency of these affections among children in the northern and eastern coasts of Great Britain than in the southern is attributable to the grater rigour of the climate in the former regions. In some localities in northern Europe inflammation of the air-passages is said to prevail at times among children as an epidemic. Perhaps a somewhat exaggerated impression exists as to the greater proportion of cases of inflammation of the larynx and trachea in young children, because in them it generally causes stridulous breathing. The chink of the glottis being very small in young children does not admit of being narrowed by turgidity of the mucous membrane without the causation of stridulous breathing to a greater or less extent. Even a slight catarrhal affection of the larynx and trachea, by exciting spasm, causes stridulous or 'croupy' breathing in a very young child, whereas a somewhat acute inflammation accompanied by considerable swelling of the same parts often runs its course in the adult without producing noisy breathing or alarm.

TREATMENT.—The treatment of diphtheritic croup is described in the article *DIPHTHERIA*.

Inflammation of the larynx and trachea, like inflammatory affections of the other parts of the air-passages and lungs, requires to be treated by antiphlogistic measures. When the inflammation is acute, active remedies are called for. Some physicians do not hesitate in such cases to bleed from the jugular vein, taking as much as three ounces of blood from a child two or three years of age. Others, including the writer, abstain from this heroic proceeding, under the conviction that although it often produces apparent temporary benefit, it is a benefit always fraught with evil. The strength is dangerously reduced; a fatal issue may be precipitated; and when recovery does take place, the course of convalescence is slow and difficult. It seems safer, and every way better, to subdue the inflammation by blisters and carefully watched doses of ipecacuan and tartar-emetic. If the affection be only moderately sthenic, it is prudent first to use the ipecacuan by itself: there are many cases, however, in which the antimonial must not be withheld. Too large a dose of tartar-emetic may give rise to alarming depression. Should such a state be induced, the best means of averting danger is watchfully to administer a little brandy, and apply a small blister—say an inch and a half square—over the sternum about two inches below the manubrium, a warm moist linseed poultice being placed over it for three or

four hours. Even when no depression has been occasioned by drugs, a succession of small blisters to the chest is of great use. Signal benefit is often obtained by a short and smart purging with calomel and scammony. In all cases, the legs must be kept enveloped in warm wrappings, moist warmth being preferred if it can be unflatteringly maintained.

In most cases, the breathing is subject to dyspneæal paroxysms arising from spasm of the glottis. The muscular relaxation which follows the emetic action of ipecacuan or tartar-emetic generally relieves this spasm with rapidity and for some hours. The vomitive effort is also useful in another way—in clearing the air-passages from dangerously accumulating mucus, and so admitting more air into the lungs. When bronchitis and bronchopneumonia are associated, as frequently happens, with the laryngeal and tracheal inflammation, the treatment is the same as that which has been already described. In protracted cases, and in weak children, it is nearly always necessary to give, for a longer or shorter period, brandy or some other alcoholic stimulant. Ammonia too is generally indicated. The extent to which stimulants are demanded varies with each case, and also with the varying circumstances of each case. Milk ought to be the principal aliment. Beef-tea, and arrowroot made with milk or with brandy, may also be given from time to time.

Should diphtheria be prevalent when we have under treatment cases of common inflammatory sore-throat, we must be specially on the outlook for the supervention of the former. Not in cases of simple inflammatory sore-throat only, but still more in the sore-throat of scarlatina and measles, diphtheria frequently supervenes as a secondary disease, suddenly declaring itself by an exudation of false-membrane in the air-passages. A new principle of treatment must be adopted when diphtheria engrafts itself on the original inflammation. We have then to treat an asthenic general disease as well as the throat-affection.

The possibility of the supervention of diphtheria, with its accompanying prostration of strength and dyscrasia of the blood, is another argument in addition to those already mentioned against the abstraction of blood in the common laryngo-tracheal inflammations of young children.

[The article on *DIPHTHERIA* should be read in connection with this article.]

JOHN ROSE CORNACK.

CROUP, FALSE.—A term commonly applied to laryngismus stridulus. See *LARYNX*, Diseases of.

CROUPOUS, CROUPY (Scot. *croup*, to crouch).—These terms were originally employed with reference to the peculiar crowing or stridulous character of the respiration, cough, and voice in certain affections of the larynx, and signified 'belonging to croup' in its clinical relations; for example, 'croupy cough,' 'croupous symptoms.' When morbid anatomy demonstrated the occurrence of a florid exudation or false membrane upon the affected

surface in a special form of croup, the word 'croupous' was used also to designate this false membrane; thus, 'croupous exudation' and 'croupous membranes.' The application of the term was afterwards further extended; and it is now employed to indicate the process that leads to a fibrinous exudation in any situation whatever; such as 'croupous inflammation,' and 'croupous pneumonia.' Thus the words "croupous" and 'croupy,' which were originally associated with peculiar sounds, have come in a remarkable manner to express certain physical, chemical, and microscopical characters in the products of inflammation. See CROUP, DIPHTHERIA, and INFLAMMATION.

CROWING CONVULSION.—A popular synonym for laryngismus stridulus. See LARYNX, Diseases of.

CRURA CEREBRI, Lesions of.—From anatomical and physiological considerations we should be prepared to find that a solution of continuity of the crus cerebri would interrupt the sensory and motor tracts for the opposite side of the body. And, further, as the roots of the third nerve pass through the inner aspect of the crus to their nucleus underneath the aqueduct of Sylvius, there is considerable danger of their being implicated in a lesion of the crus.

Hence we should expect in consequence of such a lesion, a form of alternate paralysis, viz, oculo-motor paralysis on the side of lesion, and paralysis of voluntary motion and sensation on the opposite side. A typical instance of this form of paralysis has been put on record by Weber (*Med. Clin. Trans.* 1863) In this case there was oculo-motor paralysis on the side of lesion, and complete paralysis of voluntary motion and partial paralysis of sensation on the opposite side. The partial escape of the sensory tracts is accounted for by the fact that the sensory tracts are situated more to the outer and back part of the crus, and hence tend to escape destruction from a lesion situated in such a position as specially to endanger the continuity of the third nerve.

Vaso-motor paralysis on the hemiplegic side also occurs in a marked degree, and the temperature of the paralyzed side may be two or three degrees above that of the other.

D. FERRIER.

CRUSTA LACTEA (*crusta*, a crust, and *lactea*, milk-like); milk-crust—A synonym for eczema pustulosum of the face and head, met with in infants at the breast. See Eczema.

CRUVEILHIER'S PARALYSIS.—A synonym for progressive muscular atrophy. See MUSCULAR ATROPHY, Progressive.

CUPPING.—This is a mode of treatment sometimes employed to relieve congestion or inflammation of internal parts by drawing blood to the surface of the body. When the blood thus attracted to the superficial parts is actually abstracted from the body by means of incisions, the operation is called wet-cupping, and this has been described in the article BLOOD, Abstraction of. We shall here describe dry-cupping, in

which no scarifications are made, the blood being simply drawn towards the surface by atmospheric exhaustion. hyperæmia of the subcutaneous parts or organs being thereby relieved.

Formerly cupping was extensively practised, but of late years it has fallen into disuse. In some respects it serves the purpose of, but has a more powerful effect than, counter-irritants; rapid and marked results being sometimes produced upon the circulation of inflamed or congested tissues.

MODES OF APPLICATION.—Dry cupping is performed as follows:—The flame of a spirit-lamp, being allowed to burn for an instant in the dome of a cupping-glass, is quickly withdrawn, and the cup is then rapidly and evenly applied to the skin over the affected part. The heat expands the air contained in the glass envelope, and, owing to the contraction which ensues on cooling, the skin is forcibly sucked up into the cup. It is well first to sponge the skin of the selected spot with hot water, so as to render it more supple and vascular; slightly moistening the rim of the cupping-glass helps to increase the degree of exhaustion.

An excellent modification of cupping, which has been demonstrated to the writer by Dr. Quain, is practised in the following way:—Instead of allowing the cup to remain stationary after its application to the skin, as is usual, the operator dexterously slides it to and fro along the surface. When the operation is to be thus performed the amount of surface drawn into the glass must not be considerable. In this way a large tract of skin may be quickly rendered hyperæmic without effusion of blood into its meshes, as happens when the cups are stationary.

PRECAUTIONS.—Cupping-glasses should be applied where the skin is thick and cushiony, as over the loins, nape of the neck, pectoral region of the chest, &c. and not where bony prominences, or other irregularities, are likely to interfere with complete exhaustion. The edges of the glasses should not be so hot as to burn the skin.

USES.—Cupping may be advantageously employed in sthenic cases of cerebral congestion, the cups being applied to the nape of the neck; in hyperæmia of the spinal cord; and in inflammation or congestion of the lungs, kidneys, or other viscera. In renal ischæmia it is eminently serviceable. This may be owing to the fact that the blood supply of the skin of the loins is in intimate relation with that of the kidneys; the vascular supply to those organs being thus directly and immediately influenced.

ALFRED WILTSHIRE.

CUTIS, Diseases of. See SKIN, Diseases of.

CUTIS ANSERINA (*cutis*, the skin, and *anser*, a goose). A state of roughness of the skin, resembling that of a goose when plucked, produced by prominence of the pores or follicles. It is due to contraction of the muscular structure of the corium, and is commonly occasioned by cold.

CYANIDES, Poisoning by.—See ANTIDOTE; and PRUSSIC ACID, Poisoning by.

CYANOSIS (*κναιδς*, blue).—This which is really not a disease, refers to the peculiar blue or more or less livid colour of the surface of the body, especially in certain parts, which is observed in several affections that interfere with the circulation and oxygenation of the blood. The condition is most commonly associated with, and reaches its highest development in certain forms of congenital malformation of the heart, for which consequently cyanosis is not uncommonly used as a synonym. Lesser degrees of similar discolouration are, however, not infrequently noticed in cases of cardiac disease developed after birth, and they may also accompany pulmonary affections which materially obstruct the circulation. A cyanotic appearance is also one of the obvious effects resulting from all modes of suffocation, and it is observed in the collapse-stage of cholera. The upper half of the body may become extremely cyanotic as the result of obstruction of the superior vena cava. For the pathology of cyanosis, see **HEART**, Malformations of.

CYNANCHE (*κύνν*, a dog, and *ένχη*, I strangle). **SYNON.**: Fr. *Angine*; Ger. *die Braune*.

This word is used to express an inflammatory condition of the throat, or contiguous parts, in which difficulty of breathing or of swallowing exists, accompanied by a sense or feeling of choking. The term is used synonymously, more frequently on the Continent than in England, with *Angina*; an affix, indicative of the seat or nature of the affection, being employed as a designation for each of the several forms or varieties of disease affecting the throat or adjacent parts. Such, for example, are the terms *Cynanche laryngea*, or croup; *Cynanche maligna*, or malignant sore-throat; *Cynanche parotidea*, or mumps; *Cynanche pharyngea*, or inflammation of the pharynx; and *Cynanche tonsillaris*, or quinsy. See these several diseases.

CYBTOMETER (*κύβος*, a curve, and *μέτρον*, a measure)—An instrument for measuring the absolute and relative dimensions of the chest-wall. See **PHYSICAL EXAMINATION**.

CYSTICERCUS (*κύστις*, a bladder, and *κέρκος*, a tail).—**DESCRIPTION**.—*Cysticercus* is a bladderworm furnished with a head which is distinctly visible to the naked eye. The form usually found in man is specifically identical with the so-called pork-mouse, or *Cysticercus (telæ) cellulosæ*. According to Dr. Giacomini, however, the human meale commonly displays 32 cephalic hooks, whilst the pork-mouse carries 24; moreover, in the human variety there is a greater adherence of the meale to its investing capsule. The only other form of *cysticercus* at present known to infest the human body is the slender-necked bladder-worm, or *Cysticercus tenuicollis*. An son.

alleged example is preserved in the anatomical museum attached to King's College, London. This parasite is of frequent occurrence in the sheep.

FIG. 14.—*Cysticercus (telæ) cellulosæ*, removed from the human eye by Mackenzie, x 5 diameters. After Allen Thomas.

SITUATIONS AND SYMPTOMS.—The clinical importance of the human meale is chiefly due

FIG. 15.—Portion of meat, showing *Cysticercus*. Nat. size. After Lewis.

to the circumstance that it is apt to take up its residence in the brain and eye; those parasites occupying the cerebrum being for the most part situated in the grey or cortical substance. The only serious attempt that has been made to establish diagnostic signs by which brain-cysticerci might be detected during life is that initiated by Griesinger, who based his conclusions on data supplied by the histories of upwards of fifty cases. Symptoms are exceedingly variable. In some cases they are altogether wanting; in a second set, epilepsy exists, without mental disturbance; in a third set, epilepsy is accompanied with mania or imbecility; in a fourth set, mental disturbances may occur without epilepsy; whilst in another group there is neither epilepsy nor mental disturbance, until shortly before death, when symptoms of irritation or torpor gradually supervene. Since Griesinger has himself remarked that the epileptiform seizures due to cysticercus are in all respects like ordinary cerebral epilepsy, and since also 'the psychical disturbances have nothing characteristic about them,' the practical physician is naturally tempted to conclude that diagnosis and curative treatment are alike impracticable. The writer, however, objects to that inference, on grounds too wide for discussion here; but, as one source of encouragement calls attention to the fact that cysticerci are not very long-lived. He has demonstrated that a period of eight months is amply sufficient for the setting in of calcareous degeneration, a process which involves the speedy death of the meale. If therefore the presence of cysticerci be so much as suspected in the brain, the prospect of a natural cure is by no means hopeless. Rest, both mental and corporal, would of course tend to assist nature's efforts.

Cysticerci may develop in any part of the human body; their most frequent situation being the subcutaneous, areolar, and intermuscular connective tissues. Amongst the more remarkable cases are five recorded by Heller, and one by Greenhalgh, where they occupied the lip; by Fournier, where several occurred in a boil; and one by Dupuytren, where the parasite lodged in the great peroneus muscle. Mr. R. Davy lately recorded a case in which several were present in the arm; but the well-known multiple cases given by Giacomini, Hodges, Delore, and others, show that hundreds of meales may co-exist in the same human host. In Delore's

there were about 2,000, of which no less than 84 were found in the cerebrum! Of instances where the cysticercus occupied the eye we may particularise the cases by Windoor, Logan, Fortin, Ross, and Mackenzie of Glasgow; whilst of additional brain-cases, those given by J. Harley, Hulke, Burton, Bouvier, Fréduat, and Toynbee are particularly noteworthy.

Amongst the most recent contributions to our knowledge of cysticerci are the memoirs of Ferronetto (*Della parvicatura negli animali*, in *Annali del. R. Accad. d'Agricoltura di Torino*, 1873); of Bécolet and Giraud (*Bull. de la Soc. Méd. de Gand*, 1872), of Giacomini (*Snl. Cyst. cell. hominis e sulla Tenia med.* &c., 1874), of Lewis (*Report on Bladderworms*, &c., 1872), and of Pellizzari, as reported by Dr. Tommasi in his Italian edition of the writer's manual of the parasites of our domesticated animals (*Appendice Parasiti, &c. Vermi*, 1874). A summary of these last-mentioned researches was given by the writer in the *London Med. Record* for 1874 (p. 641). Lastly, it is important to bear in mind that small hydatids, which are also liable to take up their abode in the brain, may very readily be mistaken for cysticerci, after death; and during life they are apt to give rise to precisely similar symptoms. The writer has collected records of more than thirty cases where bladderworms occurred in the human brain. References to most of these are given in the *Bibliography* of his *Introduction to the study of Helminthology (Entozoa*, 1864; and *Supplement*, 1869). See BLADDERWORMS.

T. S. CORBOLD.

CYSTINE or CYSTIC OXIDE (*xúvris*, the bladder).—A peculiar substance occurring either in solution or in the form of small crystals in the urine, or as calculi in the urinary passages. See URINE and CALCULI.

CYSTITIS (*xúvris*, the bladder).—Inflammation of the bladder. See BLADDER, Diseases of.

CYSTS.—**DEFINITION**.—The word *cyst* (*xúvris*, the urinary bladder) is used in pathology for a closed cavity containing fluid or soft matter. The nature of the wall is unimportant; it may be newly formed or a pre-existent structure. The objects thus defined differ much among themselves, and are associated together rather from convenience than on account of any real pathological similarity.

CLASSIFICATION.—Cysts may be classified according to their structure, as simple or compound; according to their contents, as serous, mucous fatty, etc.; or according to their mode of origin. The latter, though not free from objection, is the basis of description which will be here adopted. Cysts may originate (1) from *dilatation* of previously existing closed cavities; (2) from *retention* of products of secretion; (3) from *exudation*, or the metamorphosis of exuded products; (4) as a part of *new-growth*; (5) by a *vice of development*; and, finally, (6) from the growth of *parasites*.

1. **Cysts from Dilatation**.—Spaces, normal or newly formed, in connective tissue may, by irritation and consequent excessive exudation, be converted into cysts; or the same result may happen

from the confluence of several such spaces. In proportion as the wall becomes smooth, and the shape uniform, they may be called cysts. Bursæ, whether normal or pathological, are cysts. Ganglion in the sheath of tendon is clearly a pathological cyst. To these and like structures the name *Hygroma* has been given. They all contain clear serous fluid, and are lined by an endothelium. Hydrocele, or dilatation of the tunica vaginalis testis—an affection probably always due to a low form of inflammation—is another instance. One class of ovarian cysts comes under this head, those, namely, which are due to simple dropsy of the Graafian vesicle. Tubo-ovarian dropsy, has the same explanation; and cysts of the broad ligament are enlargements of normal structures which are left as relics of the development of the ovary. The thyroid gland seems from its structure, containing, as it does, so many closed follicles, particularly disposed to this kind of cyst-formation, and this is doubtless the explanation of bronchiocele.

2. **Cysts from Retention**.—Cystic formations may result from the obstruction of the natural outlet of a secreting organ, and the consequent retention of secretion. It is necessary that the walls of the secreting cavity should admit of enlargement, and that the tension should not become so great as to check secretion.

All secreting glands present instances of such cysts. The sebaceous glands of the skin are particularly liable to obstruction of their duct, and in this way are formed sebaceous cysts, miliaria, and comedones; the contents of which are sometimes epithelium and the products of normal secretion, sometimes abnormal products, such as pus. See FOLLICULAR DISEASES.

The glands or mucous surfaces are liable to similar obstructions, and *mucous cysts* result, such as are sometimes seen in the mouth. Larger cysts in the mouth (*ranula*) result from the obstruction of the ducts of the salivary glands, or are perhaps connected with an abnormal production of gland-substance. The stomach very frequently, other parts of the intestinal canal more rarely, show similar cysts, which, when they project and become complicated in structure, are called polypi. They are occasionally seen on the larynx and trachea. In no part are mucous cysts more frequent than in the uterus, where indeed, similar formations, the *ovula Nabothi*, must be regarded as normal. The varieties here met with have, as Virchow has pointed out, a close analogy with the various forms of retention-cysts in the skin.

In the mamma, cysts may result from the cutting off of portions of the gland-follicles, but the cysts contained in mammary tumours are not always formed in this way, some being part of new growths. In the testicle obstruction and cutting off of seminiferous tubes may lead to small cysts, but these are more often connected with new growths. The curious cysts known as *spermatoceles*, containing spermatozoa, appear to arise from a similar dissection of detached portions of testicle-substance, which, by an error of development, have failed to become connected with the excretory ducts. The testicle is also liable to a general cystic degeneration, usually called *cysto sarcoma*. Cysts of the kidney are of various

kinds, but many, no doubt, both large and small, result from the dilatation of uriferous tubules and capsules of glomeruli when their outlet is obstructed, as occurs in the cirrhotic form of Bright's disease. The origin of the very numerous microscopic cysts has been much disputed. The writer inclines to the belief that they arise from moniliform contraction of the uriferous tubes, especially such as contain the hyaline cylinders, known as fibrinous casts. Another form of cystic disease of the kidney is developmental. In this the whole of the organ is converted into a mass of cysts, and is usually much enlarged. This condition may be congenital, and the organ may be so large as to obstruct parturition. It is attributed by Virchow to inflammation of the calyces during intra-uterine life.

To guard against a common error of language, it should be pointed out that the condition of the kidney which results from the obstruction of the ureter, or of the urinary passages lower down, though sometimes called cystic dilatation of the kidney, is not properly a case of cyst-formation, and is better called *hydronephrosis*.

3. **Cysts from Hæmation.**—Exuded materials, such as blood and inflammatory products, may, by a process of degeneration, central softening, and external fibrous formation, become converted into imperfect cysts, as is seen in the metamorphosis of a blood-clot in the brain, and in the termination of some abscesses. But since the accumulation of fluid does not go on continually, the tension in such cavities is slight, and they do not approximate to a globular shape.

4. **Cysts from New-Growth.**—In many forms of new-growth cysts are produced, but not always in the same way. Sometimes, as in myxoma and enchondroma, they result from softening of portions of new-growth already formed. In many sarcomata, the production of new tissue goes hand in hand with that of cysts, and is sometimes effected as in glandular organs, by the formation of new follicular structures without an outlet, sometimes by new-growth into the dilated cavities. Polypoid or pedunculated growths on a free surface may sometimes, by the fusion of their extremities, enclose spaces which become converted into cysts. We do not, however, find cysts forming by themselves a new-growth of so definite a character as to deserve a separate name.

5. **Developmental Cysts.**—These include (a) *compound ovarian cysts*; (b) *dermoid cysts*. Cysts are met with in the ovary which come under none of the definitions just given, viz., the so-called *compound multilocular cysts*, which constitute the well-known formidable cystic disease of the ovary, and sometimes produce tumours of immense size. In these the originally simple primary cyst appears to become complicated by the formation in its walls of secondary cysts, which may encroach upon or project into the primary. Again there may be papillary growths starting from the inner wall of the primary cyst, which either fill it up, or by fusion enclose spaces, which become secondary cysts. Very complicated structures thus result. The contents may vary in consistence and colour, from clear, pale, albuminous liquid to gelatinous matter, and

may be stained through hæmorrhage, or purulent through inflammation. The origin of these structures, which have no precise parallel in other parts of the body, is extremely obscure. It is not even certain whether the primary cysts commence, as might seem *prima facie* highly probable, in the Graafian follicles; but they are plainly due to an error of development, possibly beginning in early intra-uterine life, and are not set up by any external causes. The presence of a tubular gland-tissue, such as is found in the rudimentary, but not in the perfect ovary, confirms this view, by throwing cyst-formation back into an early stage in the development of the organ.

In another, but rarer form of cystic disease of the ovary, equally due to an error of development, and sometimes congenital, the whole organ is found converted into a mass of small cysts, with no striking inequality of size. This variety resembles one form of cystic disease in the testicle and kidney.

Dermoid cysts are those containing sebaceous matter, and which are lined by a layer of flat cells resembling epidermis. The wall may be complicated with connective tissue, forming papillæ resembling those of true skin, and may contain hairs, sebaceous glands, either in connection with them or unattached, and sudoriparous glands. The accumulation of fatty matter within the cysts is doubtless the result of the continuous activity of the sebaceous glands, the products of which cannot escape. Large masses of hair may also be found, from continuous growth, and there are often numerous detached epidermic scales. Such a cyst has only the characters of a portion of skin, which might be imagined invested and included by the growth of the surrounding parts in an early stage of development—an explanation formerly entertained.

These simple dermoid cysts are sometimes complicated by containing teeth, it may be in very large numbers (*dentigerous cysts*), but since teeth may also be regarded as cutaneous products, the cyst may still have originated in the skin. This explanation no longer holds, however, when masses of bone are found, sometimes serving for the attachment of teeth, sometimes separate; as well as other tissues, e.g. nervous tissue and striated muscle. Cysts with this variety of contents have been called *proliferative*. Dermoid, dentigerous, and proliferative cysts appear to be always congenital structures, but may show further growth and development in after-life. At least two-thirds of the known cases have occurred in the ovaries. Next to these organs, the testicles are the most frequent seat, but these cysts have been also found in other parts of the body-cavity, in the mediastinum, lung, and even within the skull. The origin of these growths is extremely obscure; but it is desirable to reject entirely the hypothesis that a mixed tumour of this kind can be the remains of an undeveloped fetus included in the perfect individual; a hypothesis rendered improbable by the extreme irregularity of the tissues produced, the teeth, for instance, sometimes numbering one hundred or more. It would rather appear as if a portion of embryonic tissue, from the upper and middle germinal

layers, became misplaced at an early period of development.

6. Parasitic Cysts.—Several parasitic animals infesting the human body may appear in an encysted form, and may resemble in appearance true pathological cysts. The commonest, the larval form of *Tenia echinococcus*, or *hydatid cyst*, is known by its laminated wall, and by containing a fluid which is not albuminous, but holds in solution sodium chloride. *Cysticercus cellulosus* has a transparent wall and clear contents. The other encysted parasites are either very small, as *Trichina spiralis*, or unimportant.

CONTENTS OF CYSTS.—The serous cysts and hygromata contain an albuminous fluid like that of serous cavities, which may hold enough fibri-

nogenous material to coagulate spontaneously. Leucocytes may also be present. If inflammation be set up the proportion of albumin and of leucocytes becomes greatly increased. In the fluid of mucous cysts mucin is contained; in that of colloid cysts, little-known substances which are allied to gelatin. Sebaceous cysts contain neutral fats—sometimes hard, sometimes fluid, and cholesterolin. Both mucous and sebaceous products may harden into concretions, and even become calcareous. In renal cysts uræa has been found; in biliary cysts, bile-pigment; and in general the products of special secretion may be found in cases of retention, at least in early stages, but if retention last too long, special secretion may cease. Various exceptional contents have been already enumerated. J. F. PAYNE.

D

DACTYLITIS (δάκτυλος, a finger). A term meaning inflammation of the finger. It is applied to syphilis and struma of that organ, as in the terms dactylitis syphilitica, and dactylitis strumosa.

DANDRIFF, or Dandruff (from two Saxon words signifying *itchiness* and *foulness*).—**SYNON :** Furfur; Scurf of the Head.—Dandruff is met with in pityriasis, chronic eczema, and lepra vulgaris or psoriasis of the scalp.

DANDY FEVER.—A synonym for Dengue. *See* DENGUE.

DARTRE (Fr.).—This term is the French equivalent of the word *tetter*, and is applied to a variety of cutaneous diseases, without strict limitation.

DAVOS, in North Engadine, Switzerland. A dry, cold, bracing, winter-climate. Altitude, 5,177 feet. Season, October to March. Winds, N.E. and S. *See* CLIMATE, Treatment of Disease by.

DAY-BLINDNESS.—A disorder of vision, characterised by the patient being unable to see during the day; also called Nyctalopia. *See* VISION, Disorders of.

DEAFNESS.—Loss of the sense of hearing. *See* EAR, Diseases of, and HEARING, Disorders of.

DEATH, Modes of.—The proximate causes of death, whether resulting from natural decay, disease, or violence, may be reduced in ultimate analysis to two, namely, first, cessation of the circulation; and, second, cessation of respiration. On the continuance of these functions, and particularly of the former (if specialisation is possible where all are essential) life of the body as a whole, or of the individual tissues and organs, depends. These functions may cease from causes

directly operating on their mechanism, but they may also be brought to a standstill by causes operating indirectly through the nerve-centres which regulate them. Hence it is usual, in accordance with Bichat's classification, to describe this as a third mode of death; so that we speak of death beginning at the *heart*, death beginning at the *lungs*, and death beginning at the *head*. This classification is convenient; for though death beginning at the *head* is, in reality, death from failure of the respiration or circulation, or of both, through paralysis of the vital nerve-centres, yet the affection of the nervous system is the primary fact, and the phenomena are sufficiently distinct and characteristic to require separate consideration. It must, however, always be borne in mind that, owing to the interdependence of all the vital functions, there is no such sharp line of demarcation, in reality, as we, for convenience' sake, make in theory between the various modes of death.

I. Death from failure of the Circulation.—This may be (1) sudden, as in *syncope* and *shock*; or (2) gradual, as in *asthenia*.

(1) *Sudden failure of the Circulation.*—As the circulation of the blood depends on the difference in the pressure in the arteries and veins, the circulation will be brought to a standstill by any cause which annihilates, or very greatly lowers, this differential pressure. The cause may be in the heart, or in the vessels, or in both.

(a) *In the heart.* As the action of the heart is the chief factor in the maintenance of arterial tension, any organic or structural disease of the heart, rendering it incapable of propelling its contents into the arterial system, will naturally result in cessation of the circulation and death. Under this general head are to be classed all diseases of the heart and its annexes.

But apart from structural disease, the heart may suddenly be made to cease through nervous

influence. The heart may be inhibited, or be made to cease finally and for ever either by central causes, such as violent emotion, or a blow on the head; or by reflex inhibition, as in the case of a violent blow on the epigastrium, or sudden irritation of the sensory nerves of the stomach, as in corrosive poisoning, and even in the ingestion of a large draught of cold water when the system is overheated.

Death from sudden cessation of the heart's action is death from *agony*. Momentary cessation of the heart's action is transient syncope or fainting. There is sudden loss of consciousness, due mainly to the cessation of pressure in, and anemia of the cerebral centres.

(b) In the *vesels*. Rapid fall of the blood-pressure, and cessation of the circulation, will naturally be brought about by rupture of the vessels, either from injury or disease, causing death by hæmorrhage. But besides actual rupture of the vessels, the vascular area may in certain conditions become so enlarged or dilated that we may practically have death from hæmorrhage without any loss of blood externally. This is what we observe in death from *shock* or *collapse*. In certain conditions, such as that resulting from blows on the abdomen, the vascular area of the abdomen and viscera may become so dilated as practically to retain almost the entire volume of blood in the body. Hence, even though the heart may be acting, yet the circulation throughout the body generally, and especially in the extremities and superficially, is practically *nil*.

The individual may, however, retain his consciousness, and thus he differs from a patient in a state of syncope. But very frequently in cases of blows on the abdomen, there is not merely reflex dilatation of the abdominal vessels, but also reflex inhibition, for a time at least, of the heart, so that we have syncope and shock co-existing. But the symptoms of syncope may pass off, leaving those of shock still remaining. Shock, like syncope, may be transient or fatal.

(2) *Gradual failure of the Circulation*.—This constitutes death from *asthenia*. This is the natural termination of life, and it is also the mode of death after wasting and exhausting diseases, cold, starvation, &c. The vital powers fade gradually, while consciousness may be retained up to the last moment.

II. Death from failure of the Respiration. —The various ways in which the function of respiration may be interrupted, and the phenomena consequent thereon, have been described under the head of *ASPHYXIA*, to which article reference may be made.

III. Death from paralysis of the vital nerve-centres—*Coma*.—As already remarked, death beginning at the head ends by paralyzing respiration and circulation. The nerve-centres situated above the medulla and pons are not essential to life except in so far as animal life is concerned, and the possibility of adaptation to surroundings. Diseases of the brain, however, are liable to prove fatal by indirect action on the medulla and pons through pressure, extension of inflammation, and the like. Certain poisons also, whether introduced from without,—such as opium and narcotics generally,—or

arising within, owing to the non-elimination of waste products, as in *uræmia*, affect the nerve-centres, both cerebral and spinal, and not only produce unconsciousness or coma, but also paralyse the respiratory and cardiac centres.

In death arising in this manner, the individual lies unconscious, reflex action becomes abolished, and the breathing becomes stertorous and ultimately ceases, death occurring quietly or in convulsions. In death from coma, in addition to the usual phenomena of asphyxia, there is, as a rule, more or less marked congestion of the cerebral and spinal centres.

D. FARRER.

DEATH, Signs of.—It is not always easy to determine when the spark of life has become finally extinguished. From the fear of being buried alive, which prevails more abroad than in this country, some infallible criterion of death, capable of being applied by unskilled persons, has been considered a desideratum, and valuable prizes have been offered for such a discovery. The conditions most resembling actual death are syncope, asphyxia, and trance, particularly the last. We cannot, however, say that any infallible criterion applicable by the vulgar has been discovered, and we do not rely exclusively on any one sign, but combine several.

The most reliable sign of death is proof of *cessation of the heart's action*. This, however, is not to be inferred from mere pulselessness, for the heart may still be beating, and resuscitation may be possible, when no pulse is to be felt in the arteries by ordinary manipulation. The use of the stethoscope is necessary, implying, of course, technical skill. Though, according to Ruyet, the heart cannot cease to beat for more than seven seconds without death, yet, considering the very slow and feeble action of the heart (8 to 10 beats per minute) in hibernating animals, which normally have a pulse of 80 to 90 per minute, it is well to regard a similar condition as possible in man, and to spend in doubtful cases some minutes, up to half an hour, in auscultation. The so-called cases of life continuing notwithstanding cessation of the circulation, as that of Colonel Townsend, or of the Indian Fakirs, are to be set down as altogether apocryphal, and not scientifically investigated.

To enable unskilled persons to determine whether the circulation continues or not, Magnus recommends the application of a tight ligature on a finger or toe. If the circulation has quite ceased, no change in colour is produced; but if circulation continues, however feebly, the extremity, in course of a longer or shorter period, assumes a livid tint from strangulation of the venous flow, while a ring of arterial anemia is observable at the point ligatured.

Cessation of the heart's action, if absolutely established, renders other indications unnecessary. As accessories they are useful, but the following signs are none of them individually conclusive taken alone. The first is *cessation of respiration*. Respiration may not be very obvious, and yet it may be going on. The popular methods of holding a cold mirror before the mouth and nostrils, and looking for indications of moisture; placing a flock of cotton wool on the lips to ascertain whether air-currents exist,

and placing a cap of water on the chest, and observing whether the reflection on its surface moves or remains still, are all well adapted for the purpose in view.

With the cessation of the circulation and vital turgor, the skin becomes ashy pale, and the tissues lose their elasticity. The eyeball becomes less tense, and the cornea becomes opaque. The pupils cease to react to light; and there is no vital reaction on the application of irritants to the skin. Though the body is dead as a whole, certain parts may continue to retain their independent vitality after somatic death. This is seen in the muscles, which may retain their electrical contractility from two to three hours after death. The existence of electrical contractility of the muscles in a body supposed to be dead indicates life, or death within two or three hours, according to M. Roenthal.

The subsequent changes which occur in the dead body not only indicate the fact of death, but aid in fixing the probable period at which death occurred. These are the following:—

(1) *The cooling of the body.*—The body after death, except under certain special circumstances, as in fatal cases of cholera and yellow fever, ceases to be a source of heat-production, and therefore is to be looked upon as an inert mass possessed of a higher temperature than the average medium, which parts with its heat according to certain physical laws. The superficial coldness of collapse, which is due to cessation of the peripheral circulation, must not be mistaken for the cadaveric coldness, for there is still an amount of internal heat which has to be parted with, and the body, cold to the touch before death, may after death rise in temperature, as the internal heat radiates. It is impossible to describe here in detail all the circumstances which modify the rate of cooling of the body, but it may be said in general that all circumstances which favour radiation, convection, and conduction of heat in inorganic bodies are equally applicable here, while the opposite conditions retard. Therefore a thick coating of adipose tissue, clothing, &c., retard cooling. The exact thermometric observations of Drs. Wilks and Taylor show that at an average temperature, and without clothing, a dead body cools at the rate of about 1° Fahr. per hour.

(2) *Hypostasis.*—After death the blood gravitates to the most dependent parts, both externally and internally, giving rise to livid discolourations, termed *hypostases*. These are liable to be confounded with ecchymoses or extravasations externally, and with the results of congestion and inflammation in the internal viscera. They differ from ecchymoses in the fact that the blood is not extravasated into the tissues, but still contained in the vessels, as may be shown by an incision into the skin. So long as the blood remains fluid, these discolourations may be caused to disappear if the position of the body be reversed; they will again form in the parts which are now the most dependent. They usually occur in from eight to ten hours after death.

(3) *Rigor mortis.*—After death the muscles become stiff, giving rise to *rigor mortis* or cadaveric rigidity. It is due to coagulation of

the muscle-plasma. This rigidity attacks the muscles usually in a certain definite order, beginning in the muscles of the neck and face, and gradually extending from above downwards. It gives way to putrefaction in the same order, so that while the upper parts of the body may be flaccid, the legs may be found rigid. It can only be overcome by tearing the tissues, and if overcomes it does not return. In this it differs from cataleptic rigidity. A certain amount of mobility is still observable at the joints. In this it is unlike the stiffness of freezing, in which all the parts are equally rigid, and crackle if bent.

The period of the occurrence of rigidity, and the length of its endurance, are extremely variable, so that no definite practical rules can be laid down. It may be said generally, however, that the greater the store of muscular energy at the time of death, the longer it is before rigidity sets in, and the longer it lasts. On the contrary, the greater the exhaustion, the sooner rigidity sets in, and the sooner it disappears. Hence rigidity is longer in appearing in subjects dying suddenly in full muscular vigour, than in those dying from exhaustion. As a rule, a period of relaxation intervenes between death and the occurrence of rigidity, but in certain cases the last muscular contraction seems to pass directly into the rigidity of death. This is seen more particularly in death during great nervous excitement, as in soldiers in the field of battle, or in suicides. The same is said to occur also in death from strychnin-poisoning and in death by lightning.

Rigidity may therefore occur immediately on death or within a few hours. It has never been observed to be delayed beyond a day after death. It may last from so short a time as scarcely to be perceptible, up to a week or more.

(4) *Putrefaction.*—After death the tissues undergo changes in colour, consistence, &c., by which they are ultimately resolved into their simple elements, included under the general term *putrefaction*. Putrefaction, however, may occur locally during life, and general septic changes may occur to some extent before death. The term, however, is not generally applied until the changes are clearly perceptible in alteration of colour, consistence, and smell. The first external sign is a greenish discolouration of the abdomen. Internally the mucous membrane of the larynx and trachea is the first to exhibit change in colour and consistence. The less compact tissues putrefy first, the fibrous tissues resist longer, and the compact tissue of the uterus resists longest of all. In process of time, however, the soft tissues become entirely disintegrated and the skeleton is exposed and gradually falls to pieces.

The rate of putrefaction is very variable, depending partly on the state of the body itself, but mainly on external conditions as to temperature, moisture, and exposure. A combination of high temperature, moisture, and free exposure, are the most favourable conditions for rapid putrefaction. A high temperature alone without moisture tends to dry the tissues, and thus to produce mummification, instead of culiquative putrefaction. Moisture alone, as when a body lies in water or moist earth, tends to produce a saponification of the tissues, more particularly the fatty, with the

formation of a substance termed adipocere (*see* ADIPACKER). The course of putrefaction can be stopped by antiseptics, as in embalming, and in certain cases of poisoning, as with arsenic, as also by freezing. Putrefaction is more rapid in air than in water, and least rapid in earth. Under ordinary circumstances and average temperatures, signs of putrefaction are clearly visible on the third day after death, commencing with the green^c hue of the abdomen. Many months elapse before the soft tissues become entirely disintegrated. The uterus has been found fit for judicial examination as long as nine months after death, where no antiseptics had been employed. When such has been the case, however, there is practically no limit to the period of preservation—witness the Egyptian mummies.

There is still much to be learnt respecting putrefaction, and it is unsafe to lay down dogmatic rules as to how far putrefactive changes shall have advanced at a given time, for even under apparently similar conditions the most extraordinary divergences have been recorded.

D. FRERIE.

DEBILITY (*debilis*, feeble). *SYNON.*: Feebleness; Weakness; Asthenia; *Fr. Faiblesse*, *Ger. Schwäche*.

DEFINITION.—The body or any of its organs are said to be in a state of debility when their vital functions are discharged with less than the normal vigour, being reduced in the amount of activity that they display, and of work that they can accomplish. The term debility is also employed in a somewhat different sense in the case of constitutional weakness of an organ, to convey the notion of vulnerability or predisposition to disease. In this acceptation, 'pulmonary debility,' for example, signifies a peculiarly delicate 'build' of the lungs, which renders them more than ordinarily liable to succumb to the causes of disease.

ÆTIOLOGY.—Debility is frequently constitutional and inherited; but it is more often developed after birth. It is most commonly due to impaired nutrition, whether this be prolonged and moderate, as in defective hygiene or chronic illness, or, on the other hand, rapid and extreme, as in acute disease. Another frequent cause of debility is abuse of the affected organ. Overuse of any part leads to fatigue, and if frequently repeated to exhaustion, the chief feature of which is extreme debility, as in cases of sustained mental exertion or of repeated strain of the heart. On the contrary, an organ may become feeble from want of exercise. Paralysed muscles furnish the best examples of this condition, but the same may be seen in all organs after unnatural rest.

SYMPTOMS.—The natural ability of the organs to perform their functions varies extremely with sex, age, previous exercise, and many other circumstances. Debility, or the loss of this functional power, is therefore frequently ill-defined; and, when unquestionably present, may vary greatly in different cases, from a condition in which fatigue comes on only somewhat earlier than usual, as in muscular debility, to a state in which the slightest exertion may ex-

haust the whole of the vital energy and the functional life of the part may cease—as is seen in the cardiac asthenia of acute fevers, and less markedly in certain chronic diseases, such as idiopathic anemia and Addison's Disease.

Debility may be *general*, affecting the whole body; or *local*, individual organs only being involved. Speaking generally, the symptoms of debility of an organ may be said to be chiefly two. These are, first, increased irritability, or an unnatural readiness of the part to respond to stimulation; and, secondly, a tendency to untimely exhaustion. The phenomena of irritability and exhaustion naturally vary with the organ involved. The symptoms of muscular asthenia are few and simple; those of digestive feebleness are more complex; and in debility of the nervous system the whole of the mental processes, as well as the functions of organic life, may be involved. For a specific account of the phenomena of each of these cases, and of debility of other parts, the reader is referred to the articles upon diseases of the several organs.

DIAGNOSIS.—Debility pure and simple is as a rule easily distinguished from disease by the absence of all evidence of organic alteration, and especially of physical signs of anatomical change. It is more difficult to separate debility from *disorder* or *derangement*, but careful observation will generally determine in the case of pure debility that the functions are normally discharged as long as the demands made upon them are not excessive.

PROGNOSIS.—Debility due to acute disease may, in the absence of complications, be expected to disappear during convalescence. If the cause have been more chronic, and be less easily removed, recovery will certainly be more slow and less satisfactory. The prognosis of inherited constitutional debility, as regards its disappearance, is nearly always unfavourable.

TREATMENT.—Debility must be treated according to its cause. If nutrition have failed, it must be restored as far as possible; and until this can be done, stimulants and suitable tonics are indicated—especially in the case of acute disease. Rest is of the first importance in most instances; and it is frequently alone sufficient to restore the vital force. In a few cases, however, the opposite line of treatment must be followed, as in muscular debility from indolence or in some forms of paralysis. Where the vital activity is low from constitutional defect, age, or sex, the condition may not be remediable; and the treatment of such cases is chiefly prophylactic. The principal indication then is to secure the subject of debility against exposure to damaging influences.

J. MITCHELL BRUCE.

DECLINE (*declino*, I decline).—A popular name for any wasting disease; it is especially associated with pulmonary consumption. The word is also applied to the period in the course of a disease when the symptoms are abating; and likewise to the time of life when the physical and mental powers are failing.

DECUBITUS (*de*, down, and *cumbere*, I lie).—The lying posture. *See* POSTURE.

DEFÆCATION, Disorders of.—On the descent of the feces, which accumulate in the sigmoid flexure of the colon, into the rectum, the associated movements necessary for their expulsion are excited. These movements are chiefly involuntary, though influenced and controlled by the will.

Some of the most important difficulties interfering with the actions of defecation arise from disorders in the *nervous system*, by which the movements are excited and directed. In injuries and diseases of the brain or cord, the control of volition, especially its influence over the sphincters, is annihilated, whilst the excito-motory movements depending on the spinal cord continue. In these cases the actions of defecation take place only when the need of expulsion arises without any power of the patient to induce or restrain them. In injuries destroying the lower part of the spinal cord, the feces escape involuntarily in varying quantities and at all times.

Serious troubles in defecation may also arise from excessive as well as from weakened action of the *muscles* concerned in this function. The sphincter may be irritable or subject to spasm, and resist too forcibly the expulsive actions of defecation (*see ANUS, Diseases of*); or the muscular fibres of the rectum may lose their tone, be defective in power, and incapable of properly extruding the feces. Patients thus situated are often obliged, when at stool, to use the finger to dislodge masses retained in the weakened bowel. An atonic condition of the rectum usually arises from over-distension. It may be produced by too free and frequent use of enemata, the quantity injected being so large as to dilate the bowel and impair the power of its muscular coat. This atonic state of the bowel is apt to give rise to fecal accumulations. Cases of this kind are not uncommon, yet the nature of the affection is liable to be overlooked. The rectum may become gradually dilated and blocked up by a collection of hard dry feces, which the patient has not the power to expel, being unable from loss of tone in the distended bowel to overcome the resistance of the sphincter to the passage of so great a body. Some indurated lumps from the sacs of the colon, on reaching the rectum, perhaps coalesce so as to form a large mass; or a quantity accumulated in the sigmoid flexure, on descending into the lower bowel, becomes impacted there. In several instances a plum-stone has been found in the centre of the mass. Such a collection gives rise to considerable distress, producing constipation, a sensation of weight and fullness in the rectum, tenesmus, and boring pains which women liken to those of labour. In cases of some duration, where the hardened feces do not quite obstruct the passage, they excite irritation and a mucous discharge, which, mixing with recent feculent matter passing over the lump, causes the case to be mistaken for diarrhoea. Injections have no effect in softening the indurated mass; they act only on the surface, and return immediately, there being no room for their lodgment in the bowel. The practitioner on passing his finger into the rectum blocked up with a large lump, which feels almost as hard as a stone. In such cases the only mode of giving relief is by

mechanical interference. The mass requires to be broken up and scooped out. After the branking up and extraction of the larger portions, injections of soap and water will be sufficient for the removal of the remainder. The persons most subject to these troubles are those enfeebled by age or disease, especially women. They may also occur in infants who have been operated on for imperforate anus, when the artificial aperture contracts or is left too small for the free passage of the feces. In these cases the distension of the bowel is sometimes excessive, and its expulsive functions are seriously impaired and weakened (*See FÆCES and CONSTIPATION*). T. B. CUMING

DIFFERESCENCE (*de*, down, and *ferveo*, I grow hot).—The decline of fever, characterised by a fall of temperature and of pulse, and by other phenomena. *See FEVER*.

DEFORMITIES.—*See MALFORMATIONS*.

DEFORMITIES OF THE CHEST.—

Under this head are included all deviations in shape from the normal chest.

Deviations from the shape of the typical thorax are appreciable by careful physical examination. Of the various methods employed for this purpose, by far the most valuable are inspection and mensuration. Although in some few cases it may be important to determine the exact amount of deformity by mensuration, there are very few deviations in shape or size of the thorax, the degree of which cannot be sufficiently estimated for clinical purposes by the eye and hand, without the aid of any special instruments for measuring.

Deformities of the chest may be due either to abnormality of the parietes; or to disease of internal structures.

DESCRIPTION.—Deviations from the form or size of the typical thorax may be either *general* or *local*; i.e. the abnormality may involve the whole thorax, or a part only.

1. General Deformities.—**1. General Diminution.**—The chest may be too small—that is, diminished in all its diameters without being in other respects deformed. Diminution of the thorax simultaneously and uniformly in its antero-posterior and lateral diameters is effected mechanically by an increase in the obliquity of the ribs. The smaller the chest (having regard to the height of the person) the more obliquely are the ribs arranged, and the more acute the angle formed between each of the true ribs (excepting the first) and its cartilage. The intercostal spaces of the true ribs are widened about the junction of the ribs with their cartilages, and at the same time the ribs posteriorly are approximated more closely to each other, the closeness of the approximation being in proportion to the diminution in the size of the thorax. The vertical diameter of the thorax is lessened by an increase in the height of the arch of the diaphragm. The very oblique position of the false ribs, and the height to which the diaphragm rises into the chest, cause several of the false ribs to lie in contact with the diaphragm, and thus no portion of lung is under these ribs. They are, practically speaking, no longer part of the chest-walls.

The costal angles are diminished in proportion

to the diminution of the size of the thorax, *i.e.* to the obliquity of the ribs. The obliquity of the ribs also causes the shoulders and the sternal ends of the clavicles to droop, and at the same time to incline forwards; the upper part of the scapula is carried by the shoulder forward, the inferior tilted backward. General and symmetrical diminution in the size of the thorax has one and only one cause, namely, small size of the lungs. Small lungs may be congenital, *i.e.* due to original conformation, or the consequence of atrophic degenerative changes incident to age. In both these cases the lungs are, in relation to the length of the ribs, disproportionately small, and as a necessary consequence, the relatively too long ribs are arranged more obliquely than they are in a well-formed chest, and the diaphragm is pushed by the abdominal organs higher into the thorax. When the small size of the lungs is due to atrophy, the supra-clavicular fossae are deepened and the vertical diameter of the chest proportionately diminished. In advanced life the congenitally small lungs are frequently reduced still further in size by the supervention of atrophic emphysema. The congenitally small lungs and the consequently small chest is one of the characteristics of tuberculosis, *i.e.* of that congenital organization in which tubercle is likely in subsequent periods of life to occur. Atrophic emphysema is especially common in those who have either manifested symptoms of tubercle in their youth, or belong to tubercular families. It is the congenitally small lungs of childhood which are prone to become the seat of tubercle in youth, and the subjects of atrophic emphysema in old age.

2. *General Enlargement.*—The thorax may be too large, increased in all its diameters, without being otherwise deformed. It is simply bigger than it should be, having regard to the height of the subject.

When the thorax is abnormally large, the ribs, instead of being more obliquely situated than natural, as they are in the small thorax, are placed more horizontally than they are in the normal thorax. The angle formed between each rib and its cartilage is greater than in health; while the intercostal spaces, especially the lower, are widened, and the ribs less closely approximated, the arch of the diaphragm is lessened in depth, and a considerable mass of lung lies under the lower false ribs, between them and the diaphragm. The chest is increased in all its diameters. The shoulders are raised. The costal angles are greater than natural.

Increase in the size of the whole thorax has but one cause, *viz.*, increase in the size of the lungs. Increase in the size of the lungs generally, and pretty uniformly, is the consequence of disease, and of one disease only, *viz.*, large-lunged or hypertrophic emphysema. When the increase in size of the thorax attending large-lunged or hypertrophic emphysema is moderate in degree, the increase in its size is effected by the altered position of the ribs; but when the lung-disease is extreme, then a certain amount of the enlargement is caused by pressure on the inside of the chest during the violent expiratory efforts of severe cough.

3. *Irregular General Deformities.*—In the de-

formities above described the antero-posterior and the lateral diameters retain more or less perfectly their normal proportion—both are increased or both are diminished; in the former case the chest is on the whole more barrel-shaped than natural, but the deviation from the normal form is not considerable. If, however, the chest-walls are from any cause unduly soft or unduly rigid, then the actually or relatively soft portions will recede during each inspiratory act, and local deformity of the chest follows. The diameter of the chest at the part where the absolutely or relatively soft portion of the parietes is placed will be diminished. The special deformities of the chest which result are due, therefore, primarily to the state of the parietes, and are not, as those previously described, secondary to conditions of the lungs themselves.

a. *Diminution in the antero-posterior diameter of the thorax.*—The antero-posterior diameter of the thorax is frequently less than that of the normal thorax, the lateral diameter being proportionately increased. The chest has an oval form—it is flattened from before backwards.

The thorax flattened from before backwards is usually associated with small lungs, but the mechanical cause of the flattened form is the want of full resisting power in the ribs and considerable strength in the cartilages. These conditions of thorax are common in the subjects of tuberculosis.

The flattening of the thorax is increased by all impediments to the free passage of air through the air-tubes. In some children suffering from even slight bronchial catarrh, the flattening of the chest is seen to be increased at each inspiration; and if the impediment to the entrance of the air to the pulmonary tissue be constant or extreme, not only is the flattening increased at each inspiration, but the sternum is also depressed, especially at its lower half below the level of the costal cartilages, and thus the antero-posterior diameter of the thorax is still further diminished in the median line.

b. *Increase in the antero-posterior diameter of the thorax.*—In rickets the cartilages of the ribs are very firm, whilst the ribs themselves are softer than natural, and especially so near to their enlarged growing ends—the softest part of the ribs; that is to say, just outside the nodule formed at the spot where cartilage is in the process of growing into bone. The consequence of the extreme softness of the ribs at this part is that at each inspiration the weight of the atmosphere presses inward the softest part of the ribs, while the sternum is borne forward by the firm cartilages. The result is great increase in the antero-posterior diameter of the thorax, and diminution of the lateral diameter at the part corresponding to the softest part of the ribs. The depression of the softest part of each rib is increased by the want of resilience of the softened structures.

A groove is thus formed in the thoracic walls just posterior to the rickety nodules; and this groove being deepened at each inspiration, the part of the lung adjacent is compressed in place of being expanded during the inspiratory act. At the same time, in consequence of the cartilages and sternum being thrust forward at

1. **Acute Primary Dementia.**—There is a form of insanity known as primary or acute dementia, which comes on rapidly without any preceding disorder, is accompanied by the most profound vacuity and abeyance of all the mental faculties, yet yields to treatment and disappears, leaving the patients sane.

Ætiology.—The patients are young persons, boys and girls,—more frequently girls. The complaint is seldom seen in any case beyond the age of 30, and chiefly in those under 20. It seems to be a collapse of all mental power, due to great physical weakness and deficient nerve-force. Owing to imperfect development, to bad food and living, or to the patients having outgrown their strength, the mental condition becomes so weakened that, with or without some moral cause, as a fright or a scolding or something apparently more trivial, or after some illness slight or severe, they suddenly or gradually present that condition which is now to be described. If the immediate exciting cause is some mental shock or fright, the symptoms may come on rapidly. If they are due to ill-health or some protracted exhausting occupation, the access may be gradual; and if it is set down to sulkiness, temper, or idleness, the measures adopted for the correction of the latter may quickly indicate the real state of things.

Symptoms.—Nothing can appear more hopeless than the appearance many of these patients present. The face is vacant, with a fatuous grin, and often the saliva dribbles continuously. The sufferer sits motionless and lost, or automatically wags the head, snaps the jaws, or moves the limbs for hours together unconscious of fatigue. Or if a limb is placed in any position, it is retained there for a time in a way that no effort of will could accomplish. There may be a repetition of some word or sentence, but all conversation is abolished, and the patient has to be fed, washed, and tended like a baby.

The physical condition of these patients is peculiar, and corresponds closely to the mental. The heart's action and the circulation are so reduced in strength that the blood in the extremities is stagnant. Hands and feet are blue with cold even in the heat of summer. In cold weather they are covered with chilblains, and great care must be taken, otherwise these will give rise to obstinate sores. The tongue is pale and flabby, the pupils are dilated. There is no rapid emaciation, for the waste here is not great; neither is sleep absent, as in mania, but it is irregular and uncertain.

Pathology.—The external physical manifestations sufficiently indicate the condition of the brain in these patients. It is the very opposite of that in acute sthenic delirious mania. In the latter there is an excessive discharge of nervous force, an hyperæmic state of brain, and rapid brain-circulation, the whole leading in a short time to death by exhaustion if relief does not come. In acute dementia we see the very opposite. The brain-action is reduced to the lowest point, and the circulation is stagnant, as in the extremities, giving rise to passive congestion and œdema.

Course, Terminations, and Prognosis.—In acute dementia there is no sudden exhaustion; but death, if it occurs, is caused, not by the

brain-disease, but by a general failure of the bodily strength, or by some low form of lung disease—phthisis, pneumonia, or gangrene. Death, however, in this disorder is the exception. When taken in time and properly treated, the majority of these seemingly hopeless cases recover, and recover perfectly.

Treatment.—The treatment of acute dementia may be carried out in a family, or even at home, if means are ample, and if the necessary measures are strictly enforced. But it may be necessary to feed the patient by force, and that for a considerable time, and relations do not always care to enforce this to the extent required. Abundant nutrition is imperatively demanded in order to restore the force that is so greatly in defect, and unless abundant nutrition is administered, there will be no recovery, but the patient will die, or sink into permanent dementia. There is not as a rule violent resistance to food, but it may be kept in the mouth without being swallowed, and care must be taken in feeding, even if a stomach-tube be not necessary. Food should be given frequently, and so a habit of taking it engendered. Stimulants, wine and brandy, will be necessary, especially in the early stages. Equally necessary is warmth; an amount of heat is required which to those in health would be oppressive, for the greatest heat of summer fails to warm the hands and feet. Warm clothing must be provided, and the circulation aided by a short sharp shower-bath, cold or tepid, and plenty of friction afterwards. Exercise is useful for the same purpose, but this is to be taken under proper supervision, for it must not be fatiguing, and due regard ought to be had to the debilitated state of the individual. In addition to the stimulus of the shower-bath, that of electricity is of great use in acute dementia. Here, and in certain cases of melancholia, marked benefit follows the application of the constant current. Of drugs the most useful appear to be steel and quinine. The former, in this as in almost every form of insanity, is a most valuable tonic; the choice of the particular preparation should depend upon the state of the patient at the time.

2. **Chronic Primary Dementia.**—Dementia, however, may be primary, yet may not be that just described. It may come on gradually; or suddenly without previous mental affection, but is in such cases connected almost invariably with disease of the brain. Its first and most prominent symptom is loss of memory. In connexion with apoplectic or epileptic attacks, or after years of drinking, the memory is found defective. This may appear quite suddenly, or may be noticed to come on gradually, being at first so slight as to cause little alarm. It may vary at different times. If a patient is kept from alcohol, the memory may gain strength, and if epileptic attacks are reduced in frequency, the same thing may happen. The prognosis in all such cases is unfavourable, for loss of memory points to decided deterioration of brain. Apart from loss of memory, symptoms of dementia or weakness of mind are occasionally found as the first indication of mental unsoundness, following a fright or shock or some severe illness. If they assume the form of acute dementia, we may have

hopes that they will pass away, but if with little disturbance of the bodily health the mind becomes weaker and weaker, the hopes of recovery are small.

3. **Secondary Dementia.**—Of dementia which is the sequel to prior mental disorder, such as mania and melancholia, little need be said. It varies in degree, but it is not in our power to remove it. It may be in our power, however, to ameliorate in a great degree the condition of such patients when, as is frequently the case, they are found in a very neglected state. Their friends think that nothing can be done or need be done, and they are allowed to lie in bed, often in a filthy condition, or roam about and get into mischief for want of care and skilled attendance. Many demented patients have far more mind than is generally imagined by the uninitiated, and can be taught to be cleanly, to take their meals in an orderly fashion, and to keep themselves tolerably neat. They are susceptible of amusement, and open to reward for good behaviour. The vital powers of demented patients are low, and they suffer much from cold. In winter their minds like their bodies are enfeebled, and with warm weather they recover somewhat of their energy. There is a tendency in many of these patients, especially women, to become very fat, and in this condition they are subject to bronchitis, and many succumb to acute attacks of this disorder. They require warmth and good diet, for it is difficult to make them take sufficient exercise.

Females, in the writer's experience, are more prone to drift into dementia than males. The latter present various types of chronic mania, with well-marked delusions; but, among private patients at any rate, there are fewer of the hopelessly demented than among the female inmates of private asylums. One cause of this may be that the mortality amongst males is greater, and thus fewer are left to reach the demented stage.

G. F. BLANDFORD.

DEMODEX (*dēmas*, a body; and *dēx* a timber-worm).—A genus of acarine parasites, established by Owen for the reception of the human pimple mite (*D. folliculorum*), which is sometimes spoken of as the *Sitonia* or *Entozoon folliculorum*. It infests the sebaceous follicles, especially those situated upon the sides and also of the nose. The body is vermiform, owing to the great length of the abdomen, but the entire animal rarely exceeds the $\frac{1}{16}$ of an inch from head to tail. Gruby and others have succeeded in inoculating dogs with this parasite, which has also been found in mange-affected animals not previously subjected to experiment. In man, when occurring in large numbers, they cause the formation of prominent pimples, which often present an unsightly appearance. Each whitish spot or enlarged follicle presents to the naked eye a terminal black point, and it contains not only full-grown animals (having their tails directed towards the opening) but also eggs, larvae, and exuviae. Their presence rarely gives rise to inconvenience other than that resulting from unsightliness. Infected persons, however, are extremely glad to get rid of them, and this may be done by the application of mercurial

ointments, by the frequent use of a caustic sublimate lotion (2 grains to 1 ounce of water), or, as the writer has found, by rubbing-in glycerine of carbolic acid after warm water fomentations. A coarser method of treatment consists in evacuating the pustular contents by small incisions and pressure. By forcibly bursting the follicles and squeezing out the contents small ugly scars are apt to be subsequently formed. See ACARUS.

T. S. CONSOLD.

DEMULCENTS (*demulces*, I stroke softly).

DEFINITION.—Substances which soften, protect, and soothe mucous membranes. They are generally of a mucilaginous character; and when applied to the skin are termed *emollients*.

ENUMERATION.—The demulcents in ordinary use are—Linseed-tea, Gum, Starch, Bread, Honey, Fig; Linseed, Almond, and Olive Oil; Glycerine, White-of-Egg, Gelatine, and Isinglass.

ACTION.—The chief action of demulcents is a mechanical one, in forming a smooth, soft coating for an inflamed mucous membrane, and thus protecting it from external irritation.

T. LAUDER BRUNTON.

DENGUE.—SYNON.: Dandy fever (West Indies); Three-day fever; Break-bone fever; Fr. and Ger. *Dengue*.

DEFINITION.—An infectious, eruptive fever, commencing suddenly, and characterised by severe pain in the head and eyeballs; swelling and pain in the muscles and joints, prone to shift suddenly from joint to joint; catarrhal symptoms; sore-throat; congested conjunctivæ; and affection of the submaxillary glands. The disease may remit, and is liable to relapse.

NATURAL HISTORY AND GEOGRAPHICAL DISTRIBUTION.—Dengue occurs epidemically and sporadically in India, Burmah, Persia, Egypt and other parts of Africa, North and South America, and the West Indies. It is not known in Britain. Epidemic visitations of dengue, extending over wide tracts of country, occur at considerable intervals, and probably depend on certain unknown atmospheric and cosmic conditions that favour its development.

ÆTIOLOGY.—Dengue attacks persons of all ages, from infancy to extreme old age. It certainly is infectious, as has been proved by many cases in which the disease has been conveyed from person to person.

SYMPTOMS.—Those characteristic of dengue are the presence of severe continuous arthritic and muscular pains; great debility and prostration; the occurrence of an initial and a terminal rubeloid or scarlet rash; fever, which is subject to remissions and relapses; the possibility that convalescence may be tedious and painful, and complicated by the continuance of general cachexia, pain and swelling of joints, enlargement of glands, orchitis, weakness of eyes, deafness, visceral disease (such as diarrhoea or dysentery of a chronic and intractable character, and hepatic derangement) boils, carbuncles, and perhaps insanity. In the female, uterine hemorrhage and miscarriage may occur.

The *incubation* of dengue is usually sudden, the patient feeling well up to the period of attack. The earliest symptom is severe pain in some

joint, probably of a finger, which rapidly extends to all the other joints and bones; and this pain during the progress of the disease often passes from one joint to the other by a sort of metastasis. Sometimes there is a period of preliminary malaise, of one or more days' duration, marked by anorexia, a sense of weariness and languor, giddiness, nausea, chilliness or rigor, severe pain in the head—localised or in the eyeballs, and pains in the body, limbs, and joints, notably of the fingers and toes. The attack is often, however, strikingly sudden, as was frequently seen in the last Calcutta epidemic, commencing with violent pains and swelling of the joints, or severe pains in the head, eyeballs, neck, and back. In some epidemics certain phenomena are more prominently marked than others.

The eruption commences on the third day. The fever is accompanied by redness of the face, which is puffy and swollen; sore-throat; congested conjunctivæ, and a general redness, like the scarlatinal rash, extending over the whole body. The tongue is red at the tip and edges, and loaded with white fur, through which the red papillæ protrude. The pulse is rapid, ranging from 102 to 120, or even 140; respiration is hurried; and the temperature rises to 103° or even 105°. These symptoms mark the occurrence of the initial fever and rash, and endure for a period varying from one day to forty-eight hours. After this the rash disappears, the fever subsides, and the remission lasts for a period of two, three, or four days. A recurrence of febrile symptoms then takes place, accompanied by a second, or terminal rash. This differs in character from the first, resembling a rubeoloid or even an urticarial eruption, often showing itself first on the palms of the hands, and in some cases resulting in profuse desquamation of the cuticle, though it may sometimes be so slight as to be barely perceptible. These symptoms gradually subside, leaving the patient weak, exhausted, and often still tortured by swelling and pain of the joints, especially the smaller ones, which may continue in this state for weeks, making convalescence tedious and painful. Or there may be repeated relapses, prolonging the suffering and protracting recovery.

VARIETIES.—The symptoms vary in different cases, as to the character of the rash, the temperature, and the muscular or osseous pains.

The rash not only varies considerably in colour, character, and duration, but it is sometimes almost absent; in other cases it is attended with so much hyperæmia and action of the skin that excessive desquamation results. This hyperæmia also sometimes expresses itself by hæmorrhage from the mouth, nose, bowels, and uterus.

The fever is sometimes accompanied by delirium, or in children by convulsions; in the latter, indeed, these occasionally initiate the disease.

Dengue occasionally assumes a *malignant form*, where the amount of poison received has been overwhelmingly large. Dr. Charles says: 'Drowsiness may have passed into coma; the temperature verges on the hyperpyretic; the heart fails, and the lungs are oedematous: while the whole surface is highly cyanotic. These cases

have been popularly termed "black fever," and are justly much dreaded.' Happily such cases are rare. Again, there are very mild forms of the disease, in which the patients are scarcely ill, and where it is not easy to decide as to their exact nature; 'A trifling sore throat and slight malaise may be all you can lay hold of till the terminal rash appears to show you what you have had to deal with; and even this may not be seen.'

COURSE, DURATION, AND COMPLICATIONS.—The period of incubation of dengue is probably from five to six days; it may be a day or two more or less in some cases.

In simple and uncomplicated cases the average period for the duration of the disease may be taken as about eight days, but it is frequently prolonged over weeks, and recovery is slow and painful, the constitution often being so much shattered that complete restoration to strength and vigour does not occur for months. It is rarely fatal. Relapses are liable to be frequent, and the patient may suffer more than even a second or a third relapse before recovery.

Some of the *sequelæ* already mentioned may remain to torture the patient and retard his recovery. Albumen is occasionally present in the urine; but it is not, as in scarlatina, especially in the cases of children, a frequent or dangerous result of the disease.

DIAGNOSIS.—The distinction betwixt scarlatina and dengue is well marked; though during the outset there is considerable resemblance between the two diseases. There is a high temperature at first in both, but it is more quickly attained, and is transient in dengue; in scarlatina it endures for several days, whilst in dengue the *fastigium* gives a temperature of 103°, or even up to 105° or 107°, and this being attained it rapidly declines. It is exceptional to find a temperature above 102° maintained in dengue. In scarlatina the period of decline extends over several days, and is marked by slight exacerbations in the evening. In dengue it occupies a few hours, and the temperature may even fall below the normal standard. The severe muscular and arthritic pains of dengue do not occur in scarlatina, and the pulse in the latter is much more rapid in the early stages than in the former. The initial rash in dengue occurs sooner than the eruption in scarlatina.

PROGNOSIS.—An attack of dengue does not confer absolute protection from a recurrence of the disease, though it does so to a great extent.

TREATMENT.—This is a specific fever, and has to run a certain course. The treatment is simple, and if judiciously directed mitigates the sufferings, and materially aids recovery.

Neither emetics nor active purgatives are necessary. They do no good, but increase the weakness and aggravate the suffering by the muscular movements necessarily induced. Moderate action of the bowels is advisable, followed by a warm carminative aperient, or an occasional dose of calomel, rhubarb, or colocynth, especially if the bowels remain confined, to which there does not appear to be any peculiar tendency, though the evacuations may be dark and often slimy, and confined at the outset. Salines, such as the acetate of ammonia, or citrate of potash

with nitric ether, combined with aconite, are good during the pyrexia. In cases of very high temperature (105° to 107°) Dr. Charles suggests cold-sponging as beneficial; he recommends it when 105° is reached. The danger to life of such a high temperature during the intense heat of the hot months in India is great; and it is then that cold sponging or the cold bath is indicated.

Belladonna seems to confer great relief in this disease; ten to fifteen drops of the tincture may be given, and two or three such doses at intervals of an hour will sometimes produce excellent effects, and afford much relief. The extract may be given if preferred, in doses of one-third of a grain; or the juice in similar doses to those of the tincture. For the pains and nocturnal restlessness, morphia or Dover's powder may be given. Liniments containing opium, belladonna, and chloroform are serviceable as external applications to the spine, back, and joints.

Tonics, and a carefully-regulated nutritious diet, are also indicated, and depletive measures must be avoided. The tonics should be of the bitter vegetable kind, such as gentian and caustic; with these may be combined a small quantity of quinine, with a mineral acid; or in some cases, the dilute phosphoric acid, combined with nuxvomica or small doses of strychnine.

Quinine is given more for its tonic than for its antiperiodic effects; though, where there is a tendency to relapses, the judicious administration of five- or even ten-grain doses may be beneficial in arresting them. Bromide of potassium is recommended by some authorities, and especially when convulsions occur in children. Alkalies, colchicum, and other remedies in use in rheumatism have been found to have little, if any, effect in relieving the pains of dengue.

As to wines, claret is probably the best, but others may be given.

For the irritation of the skin, which is sometimes very troublesome, the application of camphorated oil, and the use of warm baths have been suggested.

As in so many other diseases, especially those that occur to Europeans in tropical climates, complete restoration to health is likely to be expedited and promoted by change of air; and if the cachexia be severe after a prolonged attack of the disease, return to the patient's native climate for a season is desirable.

JOSEPH FAYRER.

DENTITION, Disorders of. — **SYNON.** : Teething; *Fr. Troubles de la dentition*; *Ger. Zahnen*

GENERAL REMARKS.—The period of cutting the teeth has been always recognised as a critical time, during which the health of young children is especially liable to become disturbed; and it has been a common practice amongst mothers to attribute every illness occurring in early life, from the irritation of scabies to the distortions of rickets, to the same baneful influence. The evolution of the milk-teeth is no doubt attended with some irritation, especially as at this period the follicular apparatus of the intestines is

undergoing considerable development and we know that, on account of the incompressibility of the nervous system in young children, any irritation is apt to be followed by general disturbance. It is no doubt also the case that local functional derangements are frequent at this period, but it is often unfair to attribute these *directly* to the irritation of an advancing tooth. One of the most common direct results of teething is pyrexia, which may be intense; and a feverish child is particularly susceptible to impressions of cold, and to the irritation of unsuitable food. Catarrhal attacks coming on at this time need not be therefore the immediate result of the condition of the gum. It is at least equally admissible to attribute them to the ordinary causes of such derangements acting upon a body rendered for the time peculiarly susceptible to injurious influences. This view is supported by the fact that diarrhoea, which is a very common complication of dentition, is especially frequent during the warmer months, when the temperature is apt to undergo rapid variations, while the dress of the child remains unchanged; and is far less common during the winter, when the temperature is more uniform, and the child is more carefully guarded against the cold.

As a rule, the first milk-tooth appears in the seventh month after birth; but dentition may begin at an earlier period. It is not rare for an infant to cut a tooth at the age of four months, and occasionally at the time of birth one tooth is found to be already through the gum. In cases where the ordinary time of weaning is anticipated, a pause generally ensues after the appearance of one or two teeth, and further dentition is delayed until the usual age. Constitutional conditions influence the time of teething. Thus tuberculous and syphilitic children cut their teeth early, while in rickety children the teeth are very slow to appear.

In the majority of cases the teeth pierce the gum in the following order—lower central incisors, upper central incisors, upper lateral incisors, lower lateral incisors, first molars, canines, back molars. A child of twelve months old should have eight teeth and be cutting his first molars, and the whole number (twenty) should be through the gum soon after the end of the second year. The order given above is not adhered to invariably. The incisors are often cut irregularly, and the first molars may precede the lateral incisors. The canines seldom or never precede the first molars.

Some infants suffer more than others from the cutting of a tooth, and it is not always in cases where the eruption of the teeth has been delayed that dentition, when it occurs, is attended with special inconvenience. On the contrary, in severe rickets, where the delay is great, the teeth are often cut with remarkable ease.

SYMPTOMS.—The phenomena which may be looked upon as natural to the process of dentition are salivation; swelling of the gum, which becomes more and more tense, hot, and painful; slight general pyrexia, with flushing of one or both cheeks; irritability of temper; and some degree of restlessness at night. These all subside when the point of the tooth appears through the gum. The complications not necessarily

attendant upon the process are high fever, inflammation of the mouth and aphthae; vomiting (gastric catarrh); diarrhoea (intestinal catarrh); cough (pulmonary catarrh); various eruptions of the skin, with, sometimes, swelling, and even supuration of lymphatic glands; and certain troubles of the nervous system, such as convulsions, quivering, &c.

The peculiarity of the pyrexia of dentition is its irregular character. It is often higher in the morning than at night, and varies in intensity in a remarkable manner from day to day. A temperature of 104° Fah. at 8 A.M. is not at all uncommon in a teething infant; indeed such an amount of fever in the morning should alone lead us to inspect the mouth, as few diseases are marked by so much pyrexia at that hour of the day. It is important in practice to bear in mind this simple cause of elevation of temperature, for any disease in a child is apt to be complicated by teething, and much needless anxiety may be occasioned by overlooking the condition of the gum. We must not, however, in every case where the gums are swollen and tense, rush to the conclusion that they are the sole cause of the symptoms, for the most serious cerebral disease may co-exist with the eruption of a tooth. Thus, to take an example:—if we find cerebral symptoms to supervene in the course of dentition, we must most narrowly scrutinise their character, before passing them over as merely harmless indications of the general disturbance. Head-ache, delirium, vertigo, startings, twitchings, and convulsive attacks, may merely indicate functional disturbance of the brain such as is common to many disorders, and these phenomena are not necessarily symptomatic of cerebral disease; but if the bowels become obstinately confined, the pulse slow and irregular, and the respiration unequal and sighing; and if in addition there be photophobia, with sullenness and tendency to drowsiness, we may conclude that something more than mere functional derangement is present, and that there is every reason to suspect the existence of tubercular meningitis.

TREATMENT.—The treatment of the complications which occur during dentition must be conducted upon ordinary principles. Aphthae of the mouth are readily cured by the administration of rhubarb and soda, and the application to the mouth of a solution of chlorate of potash or borax in glycerine (ten grains to the ounce). Perfect cleanliness is, however, necessary, and the child's mouth should be washed out each time after taking food with a piece of soft rag dipped in warm water.

Vomiting is best checked by clearing out the stomach with an emetic of ipecacuanha wine, giving a tea-spoonful every ten minutes until sickness is produced. Afterwards a few grains of carbonate of soda may be given with one drop of liquor arsenicalis in a tea-spoonful of water three times a day. Diarrhoea should be treated on the same principle:—first a dose of castor oil to remove irritating secretions from the bowels, then a mixture containing chalk and catechu, or oxide of zinc (one grain to the dose). If afterwards the motions continue large, pasty-looking, and offensive, and are passed too frequently in the day, one drop of tincture of opium may be added to the

mixture, as there is usually in such cases too rapid peristaltic action of the intestines. In the case of either of these derangements (vomiting or diarrhoea) it is of great importance to keep the body warm, and this is most effectually done by applying a broad flannel bandage to the abdomen. The diet also should be temporarily modified, reducing the quantity of farinaceous matter that is being taken, on account of the tendency to acid fermentation of food which is set up by such a condition of the alimentary canal.

Looseness of the bowels during dentition has been looked upon by some writers as a natural method of relief to the system, and fears have been held out of grave troubles which might ensue if the looseness were too suddenly arrested. Such fears are, however, quite groundless. A catarrhal condition of the bowels should be cured as quickly as possible, especially during dentition, for it is at this time that the susceptibility to chills is so great, and the danger of severe choleraic diarrhoea being set up is therefore correspondingly threatening. In some cases of teething, where the lungs as well as the bowels are the seat of catarrh and there is a risk of bronchitis, Trousseau recommends that the intestinal derangement should not be suddenly put an end to: but even in these cases a dose of castor oil may be safely given to remove irritating matters from the canal, for, according to the writer's experience, any irritation of the bowels is apt rather to increase than to diminish pulmonary mischief.

The favourite remedy for all disorders occurring at the time of dentition is lancing the gums, but the practice is one which ought not to be pursued indiscriminately. Unless the gum be actually swollen and tense, incising it has no object whatever, for to cut the top of the gum can have no influence in promoting the development of the tooth below. If, however, there be very much inflammation and swelling, and the child seem to be in pain, relief may be obtained by lancing, but in this case the object is merely to relieve tension. Excitement of the nervous system dependent upon the condition of the mouth can perhaps be allayed by the same means; but in the case of convulsions more benefit is to be gained by the use of warm baths, cold applications to the head, and the gentle action of a mild aperient.

EUSTACE SMITH.

DEODORANTS (*de*, from, and *odoro*, I cause to smell).

DEFINITION.—The term deodorant, although it has a more extended signification, is generally used to signify a substance that destroys offensive odours.

GENERAL PRINCIPLES.—Odorous bodies are essentially volatile, and those which are offensive frequently contain sulphur in some state of combination. Deodorants usually produce the effect for which they are used by causing a chemical change in bodies to which they are applied; but sometimes their action consists in absorbing and condensing odorous substances, and thus destroying or counteracting their volatility. Substances which, like charcoal, possess this latter property may, however, indirectly produce chemical changes by bringing the odorous sub-

stances into contact with oxygen in a condensed and active condition.

Deodorants may be classed as *volatile* and *non-volatile*.

1. **Volatile Deodorants.**—These all consist of substances the action of which is immediately and exclusively chemical. Being intended to act on bodies which are themselves volatile they admit of more generally useful application than those which are not volatile.

ENUMERATION.—Chlorine and its lower oxides. Sulphurous Acid, Nitrous Acid and other oxides of nitrogen. Ozone and Peroxide of Hydrogen are the most important members of this class.

APPLICATION.—In the selection and use of volatile deodorants, it is necessary to distinguish between bodies which possess the power of destroying or removing a noxious smell, and those which merely cover one smell by another. Carbolic acid, for instance, which is a valuable disinfectant, is of little use as a deodorant, although its powerful odour may render other weaker but more objectionable odours imperceptible or indistinguishable. On the other hand, the so-called chloride of lime (chlorinated lime of the *Pharmacopœia*), while it possesses a strong and characteristic smell itself, is capable of destroying other noxious odours, and is an excellent deodorant.

The chemical action by which noxious odours are destroyed is principally one of oxidation, and therefore this class of deodorants are generally oxidising agents. Ozone, or active oxygen, is the natural deodorant contained in the atmosphere, which no doubt largely contributes to the destruction of noxious vapours in the air. Volatile oils, which emanate from the flowers and other parts of plants, in contact with atmospheric oxygen produce peroxide of hydrogen, and this as an oxidising agent possesses deodorising as well as disinfecting properties. The moderate and judicious use of perfumes may thus produce a beneficial effect, although their undue employment, by hiding more than removing what is objectionable and may be injurious to health, cannot be recommended. The preparation called 'Sanitas' is principally a solution of peroxide of hydrogen.

2. **Non-volatile Deodorants.**—**ENUMERATION.**—Among this class of deodorants are included Charcoal, Earth, Lime, Oxide of Iron, Sulphate of Iron, Chloride of Zinc, Nitrate of Lead, and Permanganate of Potash.

APPLICATION.—Although very efficient when brought into contact with the class of odorous substances referred to as noxious gases, these deodorants are less generally useful than they would otherwise be on account of their non-volatile character. Charcoal owes much of its efficacy as a deodorant to the surface-attraction and power of condensation which it possesses, by virtue of which it brings noxious gases such as sulphuretted hydrogen into contact with oxygen in a condensed and active state, so that they are burnt up and resolved into innocuous compounds, or compounds less noxious than those from which they are produced. Earth and oxide of iron, which, like charcoal, are used in the solid and dry, or nearly dry state, absorb and combine with, or promote the combination of, noxious gases, pro-

ducing innocuous products. Lime may be used either dry or in the state of milk of lime. The other substances named are used in the form of solution in water. Where large quantities of decomposing animal or vegetable matter are required to be deodorised, dry lime or solution of sulphate of iron (green vitriol) may be economically and advantageously used. T. RAWWOOD.

DEPILATORIES (*depilis*, without hair, *SYNON.*: *Pilothron*, *Rusma*).

DEFINITION.—Depilatories are agents used for destroying the hair by means of their chemical properties.

ENUMERATION AND ACTION.—Depilatories usually consist of powders, of which the chief constituents are quicklime (three parts), and sulphuret of sodium (one part), diluted with (four parts of) starch. The powder is mixed with water to the consistence of a thin paste, and laid on the part to be operated on by means of an ivory paper-knife. In from five to fifteen minutes the paste should be carefully scraped off, when the hair, shrivelled and burnt, will come with it. The skin must then be washed with fresh water, and dried, and anointed with cold cream. A strong solution of sulphuret of barium, made into a thin paste with starch, is a powerful depilatory.

ERASMUS WILSON.

DEPLETION (*depleo*, I empty). *SYNON.*: *Fr. déplétion*.

DEFINITION.—By depletion is understood (*a*) the unloading, or rendering less full, of that which is over-burdened or over-full, for example, portions of the turgid vascular system—as the portal vessels; or (*b*) excessive evacuation causing exhaustion—as in choleraic or other severe diarrhoea.

USES.—Depletion, local or general, as a therapeutic agent, may be practised in a variety of affections, such as cerebral congestion, venous turgescence, engorgement of the portal system, pulmonary congestion, renal ischæmia, or general plethora.

METHODS.—The agencies whereby depletion may be produced are blood-letting, general or local, purging, sweating, vomiting, and abstinence from food and drink.

1. **General Blood-letting.**—There is no more powerful or prompt depleting agent than general blood-letting by venesection or arteriotomy; indeed, the chief indications for bleeding are to be found where it serves a depleting purpose—as in engorgement of the right heart and venous system, visceral congestion and arterial turgescence. (*See* *Blood*, *Abstraction*.) It is seldom, however, that abstraction of blood needs to be carried to such an extent as to exert a marked depleting effect on the whole system; it is required, rather, for the relief of limited vaso-motor disturbances.

2. **Local Bleeding.**—Bleeding by means of leeches, scarifications, or cupping, may serve a very valuable depleting purpose in limited congestions, as in those of the pericardium, pleura, peritoneum, lungs, eyes, kidneys, tongue, uterus, and hemorrhoidal vessels.

3. **Purgation.**—For general depleting purposes free purging by means of hydragra-

emetics is the most efficacious agent. In cerebral, cardiac, and hepatic congestions, when it is required to give relief to turgid vessels without abstracting blood, nothing depletes so readily, efficiently, and safely as watery purges. The best purgatives are:—Elixirium, jalap, senna, scammony, sulphate of magnesia or soda, tartrate of soda, bitartrate of potash, croton oil, and gamboge; to which may be added, podophyllin, calomel, and antimony. Watery purges have the great advantage of depleting by removing serosity from the blood-vessels without the loss of red corpuscles. In cerebral congestion depletion by means of such purges is of cardinal service. In congestion of the intestinal tract arising from hepatic, cardiac, or pulmonary disease, a mercurial followed by a saline purge is of great service. Antimony has been mentioned in the above list because of its usefulness in combination with sulphate of magnesia and other saline purges. It should be remembered that it also acts as a depressant, and should only be used when such action is permissible.

4. **Vomiting**—When used as an emetic, antimony has a powerfully depressant, as well as evacuant or deploitory effect; but depression and depletion are not synonymous. The lowering effect of free purging is pronounced, and ordinarily, sufficient. Emetics may act as depoilets by evacuating the contents of, or producing a flux from, the stomach; but their depressant action is always to be borne in mind when used with this object.

5. **Sweating**—This is a less effectual mode of depletion. It may serve a good purpose, when freely induced, in lowering arterial tension, as in cases of renal disease, especially if there be pyrexia. Active exercise, the hot air (or Turkish) bath, the vapour bath, wet packing, jaborandi, antimony, and Dover's powder are the usual modes of exciting diaphoresis. Diaphoretics are often aided by copious draughts of hot fluids. The evacuant action of sweating and purging may be advantageously combined when speedy depletion is desired. The combination is valuable in certain dropsies.

6. **Abstinence**.—General depletion may be produced by abstinence from food and drink, and is sometimes employed in the treatment of aneurism, and of strangulated hernia containing omentum, the absorption of the fat of which is the object aimed at by starvation.

ALFRED WILTSHIRE.

DEPOSITS.—The term deposit had at one time a much wider extension in pathology than it has now. In accordance with the doctrine of morbid *crases* or *dyscrasias*, it was customary to regard cancers and all new-growths, the products of tubercular and scrofulous diseases, as well as those of the specific fevers and ordinary inflammation—in fact almost every kind of morbid product in the body—as 'deposited' from the blood in consequence of some alteration in its composition. In many of these cases the term deposit is still often used, even though an entirely different view may be taken of the processes leading to these morbid changes. The name remains, though the idea has departed; and this is also true of other morbid products called deposits. The

term *secondary deposits* was formerly used for what are now called pyemic or secondary abscesses, from a belief that pus was removed from the original seat of disease, and deposited in distant parts. The term *atheromatous deposit* is due to Rokitsansky, who describes this change as due to the deposition upon the arterial wall of material precipitated from the blood. In both these cases the term seems now misleading. Again, several processes which we now call degenerations or infiltrations were formerly spoken of as deposits; for example, lardaceous, fatty, and pigmentary deposit; and although these processes may now be better described by another name, it cannot be doubted that in some of them an extraneous substance is actually deposited in the tissues. The term *fibrinous deposit* was also used for the masses now known as infarctions or blocks (as for example in the spleen or kidneys) where the appearance of a mass of extraneous material is produced by the degeneration as a mass of tissue, mixed with products of hæmorrhage, inflammation, and exudation. In quite another sense the various substances precipitated from urine are spoken of as *urinary deposits*, with which we are not here concerned.

When these exceptions are made, the present use of the word *deposit* is a limited one, but is appropriate in those cases where something different from the elements of the tissue, and especially if it be an inorganic material, is found in their substance, and when it may reasonably be supposed that this material has been brought to the tissues by the circulating fluid and there deposited. The term is clearly inappropriate when the foreign matter is formed by some chemical change in the substance of the tissue-elements, but between such cases and those just mentioned it is very difficult to draw the line. We shall speak, in the sense just defined, of *calcareous, metallic, and pigmentary deposits*.

1. **Calcareous Deposits**.—All calcification of the tissues of the body, whether normal or degenerated, of inflammatory products, of new growths, or of any morbid products, appears to depend upon the deposition of lime-salts in the form of granules, this deposition taking place either within the substance of the elements, or more rarely in the intercellular substance, or, possibly, sometimes in the interstices of the tissue. Calcareous deposit takes place towards the close of life in several parts of the body, as in the walls of arteries, in cartilages and tendons, in the valves of the heart, the crystalline lens of the eye, and other parts; though in most of these cases, if not in all, some other pathological change precedes the deposition of lime. Still more frequently this change occurs in masses of dead or degenerated material, as, for instance, in organs which have partially or wholly lost their vitality, in new-growths which have reached the stage of retrogressive change, in old blood-clots, or in products of bygone inflammation. A wasted eyeball always becomes partly calcified (sometimes ossified); tumours, such as myoma and fibroma, are especially subject to calcification; venous clots which remain long undisturbed, as in the deep veins of the pelvis, undergo the same change, and become phleboliths. Old inflammatory products, as pus and lymph, seem to

become necessarily calcified if they are not absorbed; so do especially the products of chronic degenerative inflammations which have become necrotic, as seen in scrofulous lymphatic glands, and in tubercular masses in the lungs. A similar explanation applies to calcareous deposit in the walls of arteries, where the lime is generally deposited in new products which result from chronic arteritis or the atheromatous process, though lime may also be deposited in the muscular walls independently of atheroma. Necrotic masses resulting from embolic infarction are frequently calcified. Parasites of all kinds, occurring in solid organs, are liable to become surrounded by a calcified wall; a change frequently seen in hydatid cysts.

From all this it appears that calcareous deposit rarely occurs in normal healthy tissues, but is common in such parts as are dead or of deficient vitality. Its deposition must be attributed to some chemical reaction between the tissues thus altered and the lime-salts in the blood, and it is possible that the presence of an excessive quantity of lime-salts in the blood sometimes favours the change, since deposition of lime in one part sometimes coincides with removal of it from another part. In senile decay the wasting of bones goes on simultaneously with the calcifying processes just mentioned, and in some rare cases rapid absorption of bone from special disease has appeared to be the determining cause of its deposit elsewhere by a sort of *calcareous metastasis*.

2. Metallic Deposits.—Other minerals besides lime-salts are rarely found deposited in the tissues, although in cases of chronic metallic poisoning, compounds of lead, silver, and copper may be found thus deposited. Zinc and mercury are less clearly traced, but probably follow the same law. The state of chemical combination in which the metals occur is not positively known, but appears to be some combination with albumen.

3. Pigmentary Deposits.—Pigmentation as a process is discussed in the article *DEGENERATIONS*, and has been shown to depend very frequently upon the occurrence of hemorrhage and transformation of the extravasated blood. But pigment is deposited in many parts of the body, both normally and pathologically, quite independently of hemorrhage. Normally this is seen in the skin, the choroid coat of the eye, &c.: pathologically in the same situations, but in excessive quantity; and also in abnormal situations, as on the mucous membrane of the mouth. The arrangement of the pigment is in every case the same, forming minute black granules in the protoplasm of the cells around the nucleus. Its deposition and removal are regulated by causes as yet very imperfectly known, but are probably in some way dependent upon the nervous system.

The deposit of such substances as fat, lardaceous material, colloid, &c., is not a simple process, but depends either upon chemical metamorphosis of the cell, or on general pathological changes, which are dealt with in other parts of this work. J. F. PAYNE.

DERBYSHIRE NECK.—A synonym for gout, which is thus called from the prevalence of the disease in that county.

DERIVATIVES (*derivo*, I drain).

DEFINITION.—Medical appliances or remedies which lessen a morbid process, such as inflammation, in one part of the body, by producing a flow of blood or lymph to another part.

ENUMERATION.—Derivatives include—Local bleeding, Cupping, Leeches, Blisters, Sinapisms, and Setons.

ACTION.—The name 'derivative' was applied in ancient times under the belief that diseases were caused by morbid humours, which might be drawn away from the part which they were affecting. It is now used chiefly to signify the diminution of blood in an inflamed part, by increased circulation in some other vascular district, either adjoining or remote from it.

T. LAUDER BRUNTON.

DERMATALGIA (*dérma*, the skin, and *άλγος*, pain).—Pain and aching in the skin. See *NEURALGIA*.

DERMATITIS (*dérma*, the skin).—Inflammation of the skin, a term applicable to every variety of inflammation of the integument, but especially to an acute inflammation attended with exfoliation of the cuticle and copious desquamation, for example, *Dermatitis Exfoliativa*, the *Pityriasis rubra* of Boerhaave.

DERMATOLYSIS (*dérma*, the skin, and *λύσις*, a loosening).—Loosening or relaxation of the skin. See *CUTIS PENDULA* and *MOLLUSCUM*.

DESQUAMATION (*de*, from, and *squama*, a scale).—The process of separation or shedding of the epithelium of any surface. It is of most importance in connection with the skin in scarlatina, where the epidermis usually desquamates extensively.

DESQUAMATIVE NEPHRITIS.—A synonym for certain forms of Bright's Disease, applied on account of the shedding of the epithelium lining the tubules, which is characteristic of the disease. See *BRIGHT'S DISEASE*.

DETERGENTS (*detergo*, I cleanse).

DEFINITION.—Substances which cleanse the skin.

ENUMERATION.—The principal detergents are—Water, Soap, Alkalies, Ox-gall, Milk, Vinegar, Charcoal, Sand, Ontmeal, Sawdust, Pumice-stone, Oil, and Borax.

USES.—Detergents are used either to remove extraneous dirt adherent to, or epidermal scales which may have accumulated upon the skin, and interfere with its function. The chief detergent is warm water, but its action is greatly aided by such substances as soap, alkalies, borax, or vinegar, which act chemically in the removal of dirt or epidermis; or by such substances as oatmeal, sawdust, charcoal, pumice-stone, and sand, which act mechanically. Oil removes the resinous deposit left on the skin by plasters. Where the skin is tender, as in the case of the scalp, and where at the same time the detergent employed cannot very readily be removed, borax with elder-flower water may be found preferable to the more irritating soaps as a means of removing scurf.

T. LAUDER BRUNTON.

DETERMINATION OF BLOOD.—In reversed flow of blood to a part or organ, synonymous with *active hyperæmia* or *active congestion*. See *Circulation, Disorders of*.

DEVELOPMENT, Arrest of.—The causes of arrest of development are in most cases still very doubtful, and for the most important theories and observations on the subject the reader is referred to the article on *Malformations*. Such arrests may take place at any stage in the development of the embryo and of its organs; but only the most important of them, and the mode in which some typical examples are brought about, will be mentioned here.

VARIETIES.—Those which occur very early in fetal life are complex and, for the most part, incompatible with viability; whilst those which occur later often affect only one organ or a set of organs, and in some cases form no barrier to a prolonged existence. Not only must the fœtus be considered, but also the placenta and membranes in which it is enclosed *in utero*; for diseases of these lead to many forms of monstrosity, either by interference with the nutrition and respiration of the embryo, as in the case of many so-called 'true moles'; or the normal changes may be checked by adhesions between them and the fœtus. Persistence of the umbilical vesicle is excessively rare, but a patent vitelline duct is very common, and explains many of the diverticula in connection with the small intestines. A want of closure of the visceral laminae is the source of many deformities, from a simple fissure in the sternum, or a ventral hernia, to a complete anterior cleft, with the thoracic and abdominal viscera lying bare out of the body-cavity. In other cases the skin and muscles only may cover the viscera, or the muscles may not be developed. The thorax is closed before the abdomen, so that ectopia of the abdominal is more common than of the thoracic viscera. The abdomen, however, is sometimes closed in, whilst the thorax remains open, and varying degrees of ectopia cordis result; but this is rarely complete. Epispadias and hypospadias to varying extents are further examples of imperfect fusion of the ventral laminae. These may or may not be attended with displacement or deficiency of the urinary and genital organs. Similarly from an incomplete fusion of the dorsal laminae the various forms of spina bifida occur, and these are generally accompanied with an excess of fluid in the spinal canal, or hydrorachis.

The arrests in the development of the cerebro-spinal centres and of the organs of special sense are very numerous. The whole brain may be wanting, or the medulla oblongata developed and the remaining portions missing, or any given part of it may be absent or quite rudimentary. From incomplete fusion of the bones of the skull hernia cerebri or encephalocele occurs, and this is generally complicated with hydrocephalus, though the latter is frequently found as an independent and solitary affection. Coloboma and deficiency of the olfactory, optic, or auditory nerves are well-known examples of arrested development of the organs of special sense. The special malformations of the heart and vascular system, the digestive, respiratory, and urino-genital systems, will be described under the various organs; but reference must here be made to congenital fissures

leading into the pharynx (persistent branchial clefts), to the various fissures of the face and palate, to persistent cloacæ, to the numerous forms of hermaphroditism, and to imperforate anus, as all coming under this head. Varying degrees of ill-developed extremities are common, from a diminution of number in the fingers or toes, or their coalescence, to a complete absence of one or all the limbs. Finally, ducts, vessels, and openings—such as the urachus, ductus arteriosus, umbilical vessels, and foramen ovale—which normally close soon after birth, may remain patent throughout life. JOHN CUNROW.

DEVONSHIRE COLIC.—A synonym for lead colic, which has arisen from the frequency of lead-poisoning in that county, supposed to be due to the contamination of cider by lead. See *LEAD, Poisoning by*.

DIABETES INSIPIDUS (*bid*, through, *Salvo*, I flow; and *insipidus*, tasteless).—*SYNON.*: Polyuria; Fr. *Diabète insipide* or *non sucré*; Ger. *Polyurie*. A synonym for Polyuria. See *POLYURIA*.

DIABETES MELLITUS (*bid*, through, *Salvo*, I flow; and *μέλι*, a bee).—*SYNON.*: Glycosuria; Fr. *Diabète*; Ger. *Harnsückerkrankh.*

DEFINITION.—The term Diabetes, meaning an excessive flow of something, has been applied to the pathological condition indicated by an excessive flow of urine. It has, moreover, been almost wholly limited to the kind of malady characterised by the presence of a notable quantity of sugar in the urine—a condition more strictly described by the term Diabetes Mellitus. Another condition is sometimes seen where no sugar is to be found in the urine, which is, however, excessive in quantity. This is designated as Diabetes Insipidus, or better, Polyuria.

Diabetes is a malady more or less chronic, characterised by the persistent presence of a notable quantity of sugar in the urine, which is in most cases markedly abundant. It is accompanied by thirst, hunger, and bodily wasting. If unrelieved it invariably tends to death. The ordinary form of Diabetes is thus to be distinguished from certain other conditions, where, for instance, a small or hardly perceptible trace of sugar may be detected in the urine; or where, yet again, considerable quantities of that substance may be detected occasionally, and for a short time only. To this abnormal condition the term *Glycosuria* (γλυκύς, sweet, and οὐρον, urine), which is often also employed to describe artificial diabetes, best applies.

GENERAL CONSIDERATIONS.—Three important facts lie at the bottom of our knowledge of the pathology of Diabetes.¹

These are:—

I. That grape sugar is found in the healthy human body.

II. That glycogen, a substance closely allied in chemical composition to grape sugar, is also found in the healthy human body.

III. That both of these may be formed in the healthy human body.

Beyond these, certain other fairly definite propositions may be made.

¹ The discussion at length of the subject Glycogenemia, which formed part of the original article, has for want of space been here omitted.—Ed.

1. Glycogen is found most abundantly in the liver, inasmuch that, with due precautions, it can always be detected there: after a certain time sugar takes the place of glycogen, but the exact mode and time of this conversion are not known.

2. Nevertheless, it is fairly certain that the sugar called glucose can always be detected in the liver; still more certain that it is to be found in the blood; but

3. This sugar never appears in any notable quantity during a state of health in the urine.

4. As sugar is not to be found in any appreciable quantity in any other of the excretions, it follows:

5. That this sugar must disappear in the body.

6. It is commonly asserted, and, upon the whole, believed, that sugar is less plentiful in venous than in arterial blood.

7. From this, if true, it follows that sugar must be used up in the course of the circulation.

8. Where the combustion, or oxidation, occurs is not quite clear.

9. But it is plain that, from a fault in either direction, sugar may become over-abundant in the blood, namely:—

a. By over-production, or

b. By diminished consumption.

10. The over-production and the diminished consumption of sugar in the body may depend on various causes. The most notable of these are (a) an increased ingestion of saccharine material into the stomach and bowels, without a corresponding destruction; and (b) such an alteration of nerve-influences will completely modify the relative proportions of the sugar produced and the sugar destroyed.

11. With an excess of sugar in the blood, only one easy road of egress from the body is available, that is, by way of the kidneys; but this is not a sufficient outlet when there is great superabundance in the blood. Sugar may then be found in almost every one of the secretions or excretions.

12. With this unnatural discharge of sugar there is usually a corresponding discharge of urine, but not always.

13. Thus there may be no greatly increased flow of urine, yet the urine may be rich in sugar.

14. And yet, again, there may be a copious flow of urine without any sugar, as in *Polyuria*.

15. Hence the over-production or the diminished consumption of sugar in the system has no necessary connection with increased flow of urine.

16. Both the abnormal action of the liver and that of the kidneys seem in the main to depend on similar but not identical causes.

17. Both seem to be under the control of the sympathetic, but the special fibres are not the same as regards the two organs.

(a) In the case of the liver the fibres seem to originate in the medulla oblongata, to descend in the spinal cord to the lower cervical or upper dorsal vertebrae, thence to leave the cord to join the gangliated sympathetic, and so ultimately to reach the liver.

(b) In the case of the kidneys the active fibres proceed further down the spinal cord, but are ultimately connected with the great abdominal

plexus, for such it may well be called, whence the fibres proceed to the kidneys.

ÆTIOLOGY.—The classification of cases of diabetes according to causation is in very many cases practically impossible.

As to the circumstances that call the morbid processes into play, we know very little. It is certain, however, that the disease is much more frequent among men than among women, and among the middle-aged than among the very young or the very old. The disease is very much more fatal in young adults than in those over, say, forty-five. That the disease is more rife in certain districts than in others may probably be best explained by its undoubted tendency to heredity. This heredity, as in many other maladies, is peculiar; the diabetic tendency in one branch of a family being represented in another branch by various nervous disorders, especially epilepsy and imbecility.

Of the so-called *exciting* causes there are two of the first rank, namely, injury, or disease of the brain; and mental excitement, or, perhaps still more, worry. Tumours and other local brain-mischiefs sometimes give rise to a fatal diabetes. Certain mental emotions, at once powerful and prolonged, which may be epitomised in the single word strain, apparently act as exciting causes of diabetes, such as continuous anxiety, long-lasting grief, or excitement followed by reaction. Certain errors of diet—such as excessive use of hydrocarbons, especially sugar—or other interference with the laws of health, may originate a fatal diabetes, especially in those who have any hereditary tendency to the disease. It is possible that the frequency of the malady among the Jews (as noted by Seegen) may be accounted for on dietetic grounds.

ANATOMICAL CHARACTERS.—Many pathological conditions have been recorded as occurring in those who had been the subjects of diabetes, but we know little of its real pathology. In many cases nothing which can be directly connected with the diabetes has been found *post mortem*. Latterly attention has been mainly directed to the investigation of certain parts of the nervous system and of the liver itself. Perhaps the most reliable data for the ordinary anatomical appearances are to be found in Seegen's analysis of Rokitsansky's experience, embracing 30 necropsies.

Connected with the *brain and spinal cord* various lesions have been found, such as tumours of different kinds pressing on the medulla, and softening, with or without the marks of extravasated blood. In some cases extravasation has been the only morbid change discovered. In two cases under the writer's care there were extravasations of blood in the spinal canal in the cervical and upper dorsal regions, and the same was observed in another case under the care of a colleague. In one of these there was very marked softening of the cord in the regions named. In these three cases death took place suddenly. Dr. Dickinson's theory of the origin of diabetes in lesions of the nervous system, represented by enlarged perivascular spaces, the sites of existent or pre-existent extravasations of blood with destruction of the surrounding nerve tissue, is hardly tenable. The explanation

of the sympathetic system has not been more satisfactory.

Rokitansky found (in 15 out of 30 cases) that the *liver* was enlarged, hyperæmic and hard, of a dark-brown colour, with its acini imperfectly defined. The same conditions were present in the cases examined by the writer. When the disease has lasted a long time, the liver may be smaller than natural. The same would appear to hold good with regard to the cells themselves. Early in the disease, the cells, especially in the outer portions of the acini, are large, plump, and rounded, instead of angular, with large and distinct nuclei. They tend to assume a wine-red colour with solution of iodine, from the presence of unchanged glycogen. There are also sometimes found signs of active cell-growth at this early stage. Later the cells seem smaller, and as if undergoing pigmentary degeneration.

The condition of the *pancreas* in diabetes is highly interesting. In 13 out of Rokitansky's 30 cases, it was strikingly small, hard, and bloodless; and in many cases it has been found so shrunk and altered as to be hardly recognisable save by its connections. Such was the case in one instance the writer has seen, and in all his other cases the pancreas has been abnormal, usually contracted here and there, hard and knotty. In one case, however, the organ was enlarged and more succulent than usual, probably the first stage of the mischief. The occurrence of so important pancreatic changes in about one-half the cases of diabetes would seem to indicate more than a casual connection with the disease. What this connection really is remains unascertained. Klebs has associated the changes with disease of the celiac plexus. One result from the pancreatic mischief is inability to digest fat. This was seen in one of the cases referred to above.

The *kidneys* Rokitansky found diseased in 20 instances, but the changes were not uniform. Usually they presented the ordinary indications of hyperæmia, being enlarged, dark red, and full of blood. Occasionally there were signs of more extensive mischief, the substance of the kidney as well as its vessels and epithelium being involved, and the organ harder than natural. Often fatty changes occur. In one case of the writer's amyloid changes had begun in the Malpighian bodies.

The *lungs* are frequently diseased: in only 7 of his cases did Rokitansky find them normal; Dickinson only twice out of 27 instances. The changes included all stages, from acute or chronic pneumonia, to the formation of numerous cavities, or even to gangrene. In one of the writer's cases the whole of the upper lobe of one lung was converted into a huge cavity filled with solid and semi-fluid detritus, having no gangrenous odour. There had been no expectoration, and no hæmorrhage, though vessels were exposed.

The *stomach* and *intestinal canal* present little beyond the ordinary signs of recurrent or chronic catarrh—thickening, mammillation, and slaty pigmentation; erosions and ulcerations may, however, occur.

Summary.—The following sketch comprehends the more characteristic clinical features of diabetes; but there are often important variations

in individual cases, though a certain number of features are common to all:—The patient, most likely a male between twenty and forty-five, when he comes before the physician has in all probability been suffering from the disease for some time; for it usually comes on insidiously. He may say that he has been in failing health for a varying period; that he has been very thirsty, and has passed much water, having to get up repeatedly for this purpose during the night. His appetite has been more than hearty; but his food seems to do him no good, for he has been constantly growing thinner, and he feels weak and ill. On closer examination it is found that he is daily passing as much perhaps as eight, ten, or more pints of urine, light in colour and of a peculiar sweetish odour, of a high specific gravity, perhaps 1040, and containing an abundance of sugar. The skin is dry and harsh; the tongue red and glazed or slightly furrowed; the mouth dry and clammy; the lips, teeth, and gums are covered with scanty, sticky mucus; the breath is often sweetish, or it may be unpleasant from the state of the mouth; the bowels are confined; and the countenance wears an expression of weariness and fatigue.

From this point the malady may progress in one or other of two directions. Under judicious management the symptoms may ameliorate. Often the first indication of improvement is a copious perspiration; the thirst diminishes; less urine is passed; the appetite is not so ravenous; the sugar decreases in quantity; and with it the specific gravity is lessened. Emaciation ceases, and the patient begins to regain weight. This auspicious commencement may, with time and care, end in a more or less complete return to health. Unfortunately there is another side to the picture, for notwithstanding all our efforts the patient often goes from bad to worse. We fail to reduce the quantity of sugar beyond a certain point. The appetite gets more and more voracious, especially for starchy articles of food, for which the patient will sometimes lie, steal, do anything, and yet there is often no feeling of satiety. Sometimes the appetite fails, and then emaciation goes on still more rapidly. All sexual power and feeling have long ago been lost, the testes sometimes undergoing almost complete atrophy. The harsh, dry, and itchy skin becomes the seat of boils, or even of carbuncles. Often the sight is injured by cloudiness of the refractive media, especially of the lens, or by other and more anomalous changes. All this time the temperature is low, perhaps sub-normal; but towards the later stages of the malady it often rises. Such a rise indicates the accession of a formidable complication which might almost be said to be the natural termination of diabetes. This superadded mischief is a peculiar insidious kind of pneumonia, resembling acute pneumonic phthisis, and giving rise to local signs resembling those characteristic of that malady. The progress of this lung-mischief is rapid, the fever increases, and often there is irrepressible diarrhoea, sometimes of fatty-looking matter. As the end approaches, the sugar usually disappears from the urine, which may become albuminous and scanty. There may even be some œdema of the extremities. The end

often comes swiftly, and without warning, by acute pneumonia, or by what, for want of a better name, we call diabetie coma, or more slowly by gradual exhaustion. After the onset of pulmonary symptoms it is never very long delayed. Such may be said to be the ordinary course of a well-marked case of diabetes. There are cases slighter, where the history is different; but in both sets of cases there are certain symptoms, which demand further consideration than has been given them above.

The Urine.—The characteristic of the urine in diabetes is the presence in it of sugar in notable quantity, though this varies greatly in different cases. In the earliest and slightest forms of diabetes, small quantities of sugar may be passed now and again, as after a meal or the consumption of an unusual quantity of starchy or saccharine food, but the sugar may completely disappear in the interval, or may do so finally by the use of an animal diet. The sugar thus excreted is glycose of the kind called dextrose, from turning polarised light to the right, is readily soluble in water and alcohol, and easily ferments. When diabetic urine is allowed to stand in a warm place, fermentation soon sets in, gas being disengaged, and yeast deposited at the bottom of the vessel. The proportion of sugar to urine is usually from .8 to 12 per cent., but varies; the total quantity passed amounting to 20 or 25 ounces, or even more. Its presence in such proportion causes an increased specific gravity, though this is not invariably the case, inasmuch as it may vary from 1,008 to 1,060 or 1,070. Along with the presence of sugar, we almost invariably find an increase in the quantity of the urine. But neither is this an invariable feature of diabetes, for sugar may exist with a normal quantity of urine, constituting the so-called *Diabetes desipiens*. But in most cases, there is a marked increase, the quantity passed amounting to 8, 10, or 15 pints daily; and even the highest of these rates has been greatly exceeded. With an excessive amount of urine, its colour becomes lighter; sometimes it has a faint greenish tint, and when passed is quite clear. On standing there is no ordinary sediment, though, as already said, sporules of yeast may be deposited after a time. There is on the whole an excess—sometimes a large excess—of urea, and if the quantity of urine passed be small, urates or other urinary ingredients, as sulphates and phosphates, may appear. Very great inconvenience may arise in diabetic females, or even in males, by the arrest of saccharine urine about the external genitals, producing a raw or eczematous condition of the inside of the thighs and groins. The urine being also almost invariably acid, is highly irritating to the raw and swollen parts. Enuresis is common, especially at night, and among diabetic children. Albumen makes its appearance sometimes in the progress of, or in the later stages of the disease.

The Digestive Organs.—As the correlative of the unusual flow of urine we have also, as a marked and early symptom of diabetes, extreme thirst, a thirst too which cannot be satisfied, for apparently the more the patient drinks the greater is the thirst. This sensation is in some part due to the dry and clammy condition of the mouth, which it is difficult to relieve

Hunger, or even a voracious desire for food, is usually a prominent feature in diabetes, but is not invariably present, and in the later stages there may be complete loss of appetite, amounting to a loathing, especially for a restricted diet. It is often impossible to satisfy the intense craving for food, and should satiety be attained the sensation lasts but for a little time. The mouth is usually dry and parched, the saliva being scanty and tenacious. Often particles of food are retained about the teeth, and there putrefy, giving rise to unpleasant odours. The buccal fluid is almost always acid instead of alkaline, probably from the formation of lactic acid. The tongue is rarely perfectly natural. Seegen describes it as usually thickened and increased in volume, with fissures and glazed blood-red islands on its surface, which, however, may present a general coating. The teeth often fall out without pain from the retraction of the gums, and are singularly liable to caries. Digestion is usually good, except during catarrh of the stomach, which is a rather frequent condition. Constipation is the rule in diabetes, often to a troublesome extent. This arises partly from the deficiency of water in the bowel; partly also from the small quantity of fecal residue from an exclusively meat diet. Diarrhoea, on the other hand, is not uncommon, and rapidly deteriorates the patient's strength.

General Symptoms.—Emaciation is an early and marked symptom of diabetes, but not invariably so, for diabetes often occurs and persists in stout persons, without removing the obesity. These are cases of the more tractable kind, the patients being usually somewhat advanced in life. Their complete cure is seldom effected, but they do not seem to suffer greatly from the malady. Though the emaciation is in great part due to the removal of fat, and in part to the abstraction of water from the tissues, there seems to be also an actual waste of muscular substance, especially in the advanced stages of the disease. With this emaciation are associated weakness, weariness, and disinclination to exertion. These are often among the earliest symptoms of the disease, and may occur long before wasting is noticed, and increasing markedly towards the close of the malady. From various causes, one being, doubtless, weakening of the heart, oedema of the lower extremities may occur, with or without albuminuria. Gangrene of the extremities, of the scute kind, has been observed.

Respiratory apparatus.—With regard to the respiratory organs, a peculiar apple- or hay-like colour of the breath is sometimes observed, probably arising from the production of acetone mixed with alcohol. But the most serious pulmonary symptoms are those of phthisis, resulting from a more or less chronic pneumonia. This mischief is usually indicated by a nightly rise in the temperature, but otherwise may remain for a time almost latent. It is most common in the young, and towards the end of the disease. The expectorated matters may contain sugar. Gangrene of the lung, or a form of necrosis of the lung-tissues, has been noticed. With this form of gangrene the sputum may be odourless.

Skin.—The skin is usually dry and scurfy, often

extremely itchy; wounds inflicted by scratching heal with difficulty. Copious saccharine sweat is observed in a certain number of instances. There is a marked tendency to the formation of boils and carbuncles. Boils often occur early in the disease, and may give the clue to the existence of diabetes. Carbuncles occurring late in the disease may be the immediate cause of death.

Nervous System and Special Senses.—The sight is often affected in diabetes, most frequently by the formation of diabetic cataract. Operations in such cases do badly till the disease is cured, and are seldom tried, for the cataract occurs late in the disease, and advances rapidly. A form of retinitis not unlike that of albuminuria is sometimes found. Other forms of imperfect vision of uncertain origin occur in diabetes. They go by the general term of diabetic amblyopia.

Along with the physical, the mental powers fail, and all moral sentiments become blunted, which, to the friends of the patient, is not the least distressing feature in the malady.

Genital organs.—Early in the history of the disease, all sexual appetite disappears, and sexual power soon fails in the male—but with improvement this may return. In the advanced stages amenorrhoea is not unusual amongst females.

Complications.—Several of the symptoms just described are regarded by some authorities as complications of diabetes rather than as belonging essentially to the disease. Such are especially diabetic cataract and amblyopia, boils and carbuncles, and the chronic pneumonia or phthisis in which diabetes so frequently ends. Gangrene of the extremities has also been occasionally observed. Amongst the intercurrent diseases that are specially to be watched for and seriously regarded, one of the most important is albuminuria, the appearance of which may encourage a false prognosis, from the fall in specific gravity of the urine that attends it.

Diagnosis.—The diagnosis of Diabetes depends on the discovery of sugar, in notable quantity, in the urine of the patient. But before the investigation for sugar is undertaken, there have usually been observed by the patient some of the early indications of diabetes, of which the following are the most frequent, though no one definite symptom invariably heralds the disease:—1. dryness of the mouth and thirst; 2. bodily weakness and gradual emaciation; 3. dryness of skin, with itching and a tendency to successive crops of boils; 4. urination in increased quantity, the urine being of a greenish yellow tint, with the odour described; 5. defects of vision. Occasionally the attention of the patient is drawn to the state of his urine by the attraction it presents to ants, flies, and other insects; or by the formation of white spots of sugar on his dress or boots left by the urine on evaporation.

We must not forget that in true diabetes we find sugar in notable quantity. There are often present in the urine other reducing agents (such as uric acid and colouring matters), so that the amount of sugar detected must be such as to admit of no doubt whatever. Again, the presence of the sugar must be persistent, hence a single examination will not suffice for diagnosis unless sugar be found in large quantity. It may so happen that the patient when seen is

not passing sugar, from the influence of restricted diet, or from some other cause, such as pneumonia or other feverish condition. It is then best to examine the urine passed an hour or two after a meal, or even to permit the use of starchy food for a day or two, so that the constitutional proclivities of the patient may be the better ascertained. To determine the existence of sugar is not enough; it is always necessary to determine the quantity passed, so as to obtain a clue to the intensity of the disease, and to judge of the effects of treatment.

Qualitative testing for sugar.—1. *Specific gravity.*—This almost invariably exceeds that of the healthy secretion. If a large quantity of urine is being passed daily, the specific gravity of which is upwards of 1030, we have good *prima facie* grounds for concluding that sugar is present. But as urinometers are often inaccurate, this criterion is of doubtful value.

2. *Formation of torule.*—When saccharine urine is allowed to stand for a time in a warm place, sooner or later fermentation is set up, with the formation of yeast-fungus (*Torula cerevisiae*). The detection of the fungus by means of the microscope has been proposed as a test of the saccharinity of the urine. Such a test is of little use, for the spores of the ordinary mildew fungus (*Penicillium glaucum*) can hardly be distinguished from those of the yeast-fungus, and penicillium will grow on any decomposing organic matter.

3. *Fermentation.*—The fermentation of saccharine urine may be greatly accelerated by adding to it some fragments of dry German yeast, and placing it in a moderately warm place. The production of alcohol and carbonic acid which results is a certain test of the presence of sugar in the urine. This procedure, however, takes some time and is not very delicate, requiring about five parts of sugar in a thousand, or two and a half grains to the ounce, to give any satisfactory result. It is best managed as follows. Take a large test-tube, or ordinary medicine-bottle, place in it some fragments of yeast, and fill up with urine. Fit a cork with a hole bored through it with a bent glass tube, one end of which will reach nearly to the bottom of the bottle that is to contain the urine. Fix the cork firmly in the mouth of the bottle, so that the bent end of the tube shall turn away from its side, and over a wine-glass or similar collector. When fermentation begins, the carbonic acid collecting in the top of the bottle will press downwards on the fluid, which will thus be forced up through the bent tube, and fall into the wine-glass or other receiver. An important and valuable modification of this test will be noted hereafter.

4. *Moore's test or Heller's test.*—When saccharine urine is boiled with liquor potassæ the sugar is decomposed, and a compound is formed, giving its colour, black or brown, to the fluid. A convenient test-tube is filled one-third full with the urine, and an equal quantity of liquor potassæ is added. The two should then be well mixed by shaking, and the heat of a spirit lamp applied to the upper portion of the mixed fluids. If sugar be present this portion will gradually darken, the tint assumed varying in depth according to the quantity of sugar present. This test is very convenient, but it is liable to several objections,

notably these:—(a) It is far from delicate, requiring as much as three parts in a thousand, or a grain and a half of sugar to the ounce, to afford any satisfactory indication. (b) It is practically useless for quantitative purposes, though the plan has been tried of comparing the colour produced with the colours of solutions containing known quantities of sugar, as is done in the Nessler process for substances producing ammonia and its allies. (c) It is liable to two notable fallacies. (1) High-coloured urine is always darkened in tint, sometimes blackened, by boiling with liquor potassæ. (2) Liquor potassæ very often contains lead, which is liable to be converted into black sulphide, when boiled with caustic potass, if albumen or any organic matter be present in the urine. The former of these risks cannot well be obviated. The latter may, by first testing the purity of the liquor potassæ, and keeping it in green glass instead of white glass bottles.

5. *Boettger's test* consists in the action of sugar as a reducing agent on bismuth. A small quantity of urine having been poured into a test-tube, an equal bulk of a solution of carbonate of soda (one part of crystallised carbonate of soda to three of water) is to be added, and a small quantity of the ordinary basic nitrate of bismuth introduced. The whole is to be heated, when the appearance of a grey or black colour will indicate the reduction of the bismuth, and the presence of sugar. Albumen in the urine gives rise to a similar fallacy as in the last test, by the formation of a black sulphide of bismuth. Other metals, as silver, chromium, and tin, may be reduced in like manner, but by far the most convenient practically is copper, which is now almost universally employed for this purpose, as in

6. *Trommer's test*.—The usual mode of procedure is to take a drachm or two of urine in a test-tube, to add to it a few drops of solution of sulphate of copper, then to add liquor potassæ in excess, and to boil. When sugar is present a red or orange-coloured deposit of suboxide of copper should be thrown down. To this simple mode of testing there are several objections. If excess of copper be used some of the blue-hydrated oxide of copper may remain unchanged, and so give rise to confusion. If too much liquor potassæ be used it may blacken the sugar. Hence it is better to add the liquor potassæ first, then to add the copper solution drop by drop. A bluish-white precipitate forms, which dissolves on shaking. In this way a splendid blue fluid is produced. When the precipitate ceases to dissolve, neither reagent can be in excess, and heat may be applied. This solution of the blue precipitate is due to the presence of sugar, but many other organic substances have the same effect. Among the substances which possess this property, yet do not reduce the copper by boiling, is tartaric acid, and advantage of this has been taken for the production of a test-fluid not open to the above objections. The employment of this is known as

7. *Fehling's test or method*.—This testing fluid may be procured ready-made, but the following is the formula for it, as slightly modified by Pavy, and fitted for daily use:—Five grains of

sulphate of copper, ten grains of neutral tartaric acid of potash, and two drachms of liquor potassæ. A more exact formula will be given farther on. The fluid thus formed is of an intense blue colour, clear and bright. When the test-fluid is to be used, a small quantity of it should first be raised to the boiling point, because by prolonged keeping the tartaric acid undergoes change, a substance being formed from it which is capable of reducing copper, and might give rise to confusion. But if on boiling the test-fluid no copper is thrown down, the suspected urine should be added drop by drop, the mixed fluid being at the boiling point. If sugar be present in quantity it will throw down the copper in the form of a red or orange precipitate. The quantity of urine added must never exceed the bulk of the test-fluid, and the upper portion of the fluid should be heated, so as to contrast with the lower portion. Should suboxide of copper be thrown down when the test-fluid is boiled, the fluid must be filtered before adding the suspected urine, or, still better, a new fluid be prepared. To obviate as far as possible such inconveniences, the cupric and alkaline fluids should be kept in separate bottles until about to be used.

When the quantity of sugar in the urine is very small, as may occur in ordinary diabetes after long fasting or the use of a rigidly restricted diet, or during an access of fever, still more minute precautions must be taken. When, from any cause, the sugar present is less than three parts in a thousand, various anomalies may occur in the reaction. It is in such cases that the reducing power of uric acid and the urinary colouring matters assumes importance. With this small quantity of sugar the copper deposit is never red, but yellow; and we may have apparently an intermediate shade of colour from the deep blue of the copper solution through all varieties of green to yellow, with or without deposit after standing. Again, if the urine contains much phosphates, boiling with the alkaline solution may throw them down, and if at the same time the normal urinary constituents reduce some of the copper, the precipitate may roughly resemble a deposit of copper produced by sugar. It may thus be necessary to decolorize the urine, which may be done by passing it repeatedly through a filter of animal charcoal. Another difficulty is the presence of albumen in the urine, which renders the test nugatory. Accordingly in all cases, before applying any kind of test, the albumen must be removed by boiling and filtration.

Quantitative Testing for Sugar. 1. *Fehling's volumetric method*.—This method, now in common use, is founded on the fact that the proportion in which sugar reduces copper is constant. One equivalent of grape sugar decomposes exactly ten of sulphate of copper, or 180 parts by weight of grape sugar decompose 1248.8 parts by weight of sulphate of copper. This being borne in mind, and a copper solution of known strength being used, it is easy to determine the quantity of sugar in any given specimen of urine. The quantities may be calculated according to the metric system or by grains and minims. If we adopt the metric system, our fluid will consist of the following ingredients:—

Sulphate of Copper (crystals) 40 grammes.

Tartrate of Potash (neutral) 160 grammes.

Iodine Soda (Sp. gr. 1.12) 750 grammes.

Water to 1154.5 cubic centimetres.

These should be carefully mixed, or, what is better, the copper and alkaline solutions made separately, so that five cubic centimetres of each, or ten of the mixed fluids, will exactly decompose 465 grammes or 50 milligrammes of sugar.

According to the English system of measurement, Dr. Pavy's solution is the most convenient. It consists of sulphate of copper, 320 grains, dissolved in ten ounces of distilled water; and tartrate of potash (neutral), 640 grains, with caustic potash 1280 grains, also dissolved in ten ounces of distilled water. These fluids may be kept separately or mixed. In mixing, the copper should be added to the alkaline solution, not *vice versa*, to prevent the formation of any precipitate. One hundred minims of this mixed fluid are decomposed by half a grain of sugar. Only a minim measure and a porcelain capsule or other vessel, which will stand heat, are required for Pavy's solution in the procedure which is as follows:—Most specimens of diabetic urine, containing too much sugar for accurate testing, first require dilution with water, and the most convenient degree of dilution is when one-tenth of the fluid is urine. Next put ten cubic centimetres of the metric copper solution, or one hundred minims of Pavy's solution, carefully measured, in a small porcelain capsule. The fluid being deep blue is better for dilution, so as to diminish the intensity of tint. Of course this does not alter the quantity of copper present in it. The porcelain capsule with its contents is to be placed on an iron retort-stand, at such a level that the flame of a spirit lamp will easily play on the capsule. Meanwhile a pipette, graduated from above downwards, either in minims or cubic centimetres, is filled up exactly to the 0 in the graduated scale with the diluted urine. When the solution of copper is boiling, the urine is added to it from the pipette, drop by drop, stirring carefully the while, until signs are shown of a decoloration of the cupric solution. The moment all the copper has been thrown down as suboxide, and all shade of blue or green has disappeared, the addition of the diluted urine is stopped, and the quantity already used read off on the graduated pipette. To ascertain the quantity of sugar in the urine is now a simple calculation. We know how much urine has been employed in reducing the 10 cubic centimetres, or 100 minims of the cupric fluid, but these measures represent exactly 50 milligrammes and half a grain of sugar respectively. The quantity contained in the diluted urine being hence deduced, multiply this by ten, to get the quantity contained in the urine as passed. Next multiply by the total quantity of urine passed in twenty-four hours, to ascertain the full amount of sugar passed in this period. In all such analyses the sample examined should be taken from the mixed urine passed during the whole twenty-four hours. That passed at night is the richest, that passed in the morning poorest in sugar.

2. Roberts' fermentation method.—We have already noticed the fermentation method for demonstrating the existence of sugar in urine.

Dr. William Roberts, of Manchester, has also devised from it a highly accurate quantitative process. It is as follows:—

Put about four ounces of the suspected urine into a clean eight- or twelve-ounce glass bottle. Introduce a piece of dry German yeast, about the size of the point of the forefinger, but divided into small pieces. Cork the bottle with a grooved cork to allow the escape of gas. Fill a companion bottle *quite full* with the urine. Cork quite tightly, and set both aside for twenty-four hours in a warm place—the mantelpiece will do. By the end of that time fermentation will probably have ceased, and the yeast fallen to the bottom, but if not, being suspended it will not affect the specific gravity of the fluid. The specific gravity of the two specimens must now be carefully taken with an accurate urinometer, that of the unfermented bottle being taken as the standard. The fermented urine will have lost weight from two causes. 1st, the sugar which gave the increased specific gravity has been destroyed; and, 2nd, in its place have been formed alcohol, which is lighter than water, and carbonic acid, which has escaped. *Every degree of specific gravity thus lost represents a grain of sugar in the ounce of urine.* Thus, if there is a loss of twenty-five degrees of specific gravity, the urine would contain twenty-five grains of sugar in each ounce. Multiply this by the total number of ounces passed, to get the amount of sugar discharged per diem. This plan is especially useful for noting the quantity of sugar passed day by day, and can be easily undertaken by the patient or his friends.

3. Estimation by the polariscope.—A plan of estimating sugar employed a good deal abroad, depends on the power of diabetic sugar to turn the plane of polarisation to the right. The degree of rotation is in proportion to the quantity of sugar contained in the urine. The apparatus used commonly goes by the name of the *Ventke-Soleil* apparatus, from its inventors. It is best adapted for light-coloured urines. If the urine be deep in colour it requires to be diluted.

4. Estimation by specific gravity.—The rudest mode of estimating sugar is by the specific gravity of the urine. Since the methods described above were introduced, there is no excuse for its employment save as a preliminary test, which may suggest the idea of sugar in the urine. To facilitate its use tables were drawn out, but the great increase of urea often found in diabetes renders the test of but little accuracy.

PROGNOSIS, COURSE, AND TERMINATION.—The prognosis of confirmed diabetes is ever unfavourable. Amelioration is common, but a perfect cure, save in exceptional cases, is rare. Diabetes coming on suddenly and from special causes, such as injury to the head, is more likely to do well than when more gradually developed. The younger the patient, the more sugar passed the greater the emaciation and debility, the worse the prognosis. Diabetes persistent with pure flesh diet is worse than if persistent only with a free starchy or saccharine diet. Loss of appetite and of digestive power, as indicated by the condition of the feces, is of evil omen. When albumen appears in the urine in the course of diabetes, the specific gravity of the fluid diminishes, often

giving rise to a false impression to the effect that, as the specific gravity has decreased, the diabetic state must be improved. The only true test of recovery is the power of consuming ordinary mixed food with impunity; but Seegen says that out of two hundred cases he had never seen this result. But by rigid or limited dieting, the patient may live, and even enjoy life, for many years. Heredity, directly or collaterally, adds to the blackness of the out-look. Cases resulting from injury to the brain or other parts of the nervous system are often the most hopeful with which we have to deal, though by no means always so. The course of diabetes is on the whole chronic. Most frequently it develops gradually, though in some cases suddenly, and it generally lasts from six months to three or four years. In stout elderly persons it may exist much longer, especially with good digestion and a limited dietary. On the other hand, Dr. Roberts records a case which proved fatal, after a well-marked onset, in eight days—the shortest period known to the writer. Another case was fatal in three weeks, the patient being three years old. Some cases are recorded of death at still earlier periods, but these were most probably cases of long duration in an unnoticed shape suddenly developed into an aggravated form. A fatal termination of diabetes may be brought about, as already indicated, in various ways. One is by diabetic coma, not unlike the first stages of uræmia. This may prove suddenly fatal, and has been described as due to fat embolism, or to acetone in the system. In the advanced stages of diabetes, the strength being very low, comparatively slight causes may produce fatal effects.

TREATMENT.—Though we are ignorant on many points as regards diabetes, yet when we come to its treatment, we have these undoubted facts—that sugar cannot be formed out of nothing; and that the series of substances out of which it may be formed is limited. And though we cannot absolutely succeed in feeding the patient on substances which will not yield sugar, we can supply a nourishing diet furnishing sugar-forming materials in the scantiest proportion—an end best attained by a pure meat diet. But besides dietetic measures, other, though subsidiary, means may be taken to limit the formation of sugar by suitable hygienic and medicinal treatment. It is convenient to treat of these separately, though they should be employed in conjunction.

Dietetic treatment.—All authorities agree that meat should be the main constituent of the patient's food, and that starch, and cane and grape sugar, should be avoided, as well as the substances containing them. The use of fats and oils, of fruit-sugar (levulose), and of milk-sugar, is not so definitely settled. Three of the ordinary constituents of meat—gelatine, glycogen, and glycerine—being sugar-formers, the parts of animals containing these should as far as possible be avoided. It is very important in constructing a diet scale to give the patient as much variety of form as possible, the basis remaining the same. As the diet of the patient is the main factor in his treatment, it is worth the practitioner's while to study the various changes and combinations of food which may be given with impunity. (See a

long list of available dishes in the Appendix of Bouchardat's work on Diabetes.) As regards vegetables, the rule is that all green vegetables, or the green parts of vegetables, may be eaten; for where chlorophyll is abundant, starch and sugar are commonly scanty; but this rule has important exceptions, which will readily occur to the reader. Thus the green parts of asparagus and celery may be used, whilst the white portion is highly saccharine. Green artichokes may be used. Jerusalem artichokes are objectionable. Cabbage should be used before it forms a white heart. Cauliflower and brocoli are rather questionable. Scottish kale and spinach may always be used. Sea-kale is forbidden. Most fruits are forbidden, but nuts may be used if they can be digested. French beans may be used when quite green; when older the beans themselves must be removed. Haricot beans, peas, and all cereals; tapioca, sago, arrowroot, all forms of macaroni, potatoes, carrots, turnips, parsnips, and beetroot are in the forbidden list. Watercress, lettuce, and all kinds of green salad may be freely used. Cheese, especially of the poorer kinds, may be used. Cream, butter, and other fatty articles may be used in moderation, as they are only sugar-formers by virtue of the glycerine they contain. Some kinds of green pickle are useful; mustard pickle should not be used. Most mustard contains starch, but it may easily be got quite pure. To sweeten tea or coffee, mannite has been suggested; but both will soon be found more refreshing without sugar. Cocoa made from the nibs can be used. Small quantities of cold tea without milk or sugar, with slices of lemon in it, will often be found palatable, cleaning the mouth and relieving thirst. Rinsing the mouth with iced water will often give more relief than a hearty draught. Slowly sucking ice is a very good plan for relieving thirst. All sweet drinks are in the forbidden list, including most sherries and ports, though some of the former may be found nearly sugar-free. Nearly all brandies contain sugar. Light French and German wines contain little or no sugar. Gingerbeer and lemonade are very objectionable; so are champagne, sweet beer, cider, porter and stout, rum and gin. Whisky is probably the best form of spirits. The use of alcohol in these cases has been gravely questioned. Where alcohol has not been used before the onset of the disease, the patient is probably better without it; but it is quite clear that in many cases it may be taken in moderation with advantage.

There is difficulty in procuring a substitute for bread and potatoes. Three imperfect substitutes are employed, viz:—gluten bread, bran bread, and almond bread. Gluten bread as introduced by Bouchardat consists of flour out of which nearly, but not quite, all the starch has been washed. It is tough, and patients tire of it; a better form of gluten bread is made by Bonthron (Regent Street, London). This last is palatable and nearly starch-free, but does not keep well. Bran bread is now often made, in the form of biscuits or cakes; the bran should always be washed nearly free of flour. Bran bread is hardly admissible when there is a tendency to diarrhoea, but may be useful in constipation.

Almond cakes were first introduced by Dr. Pavy. They are rather rich to be eaten with meat, but used by themselves or with wine are excellent. Almond flour may now be obtained from which much of the oil has been expressed.

We pass over Dr. Donkin's skim-milk treatment of diabetes with the remark that in the hands of Dr. Donkin, and some others the method has been successful; in the hands of many eminent physicians, both at home and abroad, it has done unmitigated harm. Probably the explanation of any successful cases may be found in the fact, that in certain conditions of diabetes, milk sugar, as well as certain other substances, does not give rise to grape sugar. If milk is to be used, butter-milk or sour milk will be best. The treatment by sugar or glycerine is self-condemned.

Hygienic treatment.—In this the first and most important point is regular exercise, especially walking, not carried out to fatigue. Bouchardat has strongly advocated gymnastic exercises. These would be useful in moderation, especially in bad weather. Nothing is more grateful or beneficial to the skin after such exercise, or even without it, than a warm bath, temp. 80° to 90°, with a little common washing soda in it. In all cases, the avoidance of wet and cold is important. Flannels, frequently changed, should be worn; and it is always safer to change the clothes after the slightest exposure to damp. Little may suffice to give rise to a fatal pneumonia.

Medicinal Treatment.—This must be considered as subsidiary to dieting, but there are many cases where undoubted benefit results from drugs. Of those which have been found of real value, the foremost is opium. Yet there is no unanimity of opinion as to the mode in which opium acts, and its apparent effects are most discordant—in some cases reducing both sugar and urine without sleepiness, in others speedily giving rise to drowsiness and even apparently to coma. The varied susceptibility of different patients to this drug is very striking. Some will take 20 or even 50 or 60 grains a day with no apparent physiological effect beyond slight contraction of the pupil; others again cannot endure even a few grains. The writer's experience is decidedly in favour of opium. Codeia has been strongly recommended by Dr. Pavy as being the influential ingredient in the raw opium. He begins with doses of half a grain. Next to opium come alkalies, and especially some alkaline waters. Alkalies themselves may be given in various forms—as cream of tartar to relieve thirst, as citrate or bicarbonate of potash, or, if there is a tendency to gastro-intestinal catarrh, as liquor potassæ, with or without a bitter. The waters in most repute in diabetes are those of Carlsbad, Vichy, and Vals. An annual visit to Carlsbad, with the rigid system of regimen and dietary carried out under the resident physicians, often suffices, with due care, to keep the patient fairly well for many years.

Lactic acid has been strongly advocated by Cantani. His results seem good, but he also makes use of a most rigid dietary. Dr. B. Foster records a case where acute rheumatism seemed to arise from the use of lactic acid. Peppine

and rennet have been used, but without real advantage.

Of secondary remedial agents, the three most important are strychnine, iron, and cod-liver oil; these favour nutrition, and the cod-liver oil seems to improve the temperature somewhat. Laxatives, not purgatives, should be used for the troublesome costiveness. Mineral waters, castor-oil, or alkaline purgatives suit best.

MANAGEMENT OF A CASE OF DIABETES.—By way of recapitulation we may say a few words here on the management of a case of diabetes. When a patient comes under the care of the practitioner he must first ascertain the general state of the patient as a basis for future comparison. The patient's weight must be carefully taken, and the state of his bowels noted. The quantity and characters of urine passed should be noted daily for a short time, the patient still consuming ordinary diet. After a day or two the restricted diet should be gradually commenced, sugar and potatoes being first cut off. Next the bread should go, being first of all cut down and used toasted hard or torrefied, and this should merge into the use of bran cakes or gluten bread. Above all things, the patient must not be disgusted with his food, for this favours the secret consumption of forbidden dainties. Week by week the weight should be taken; day by day the sugar estimated, as may easily be done by Roberts' method, and the whole arranged on a card so as to be seen at a glance. Warm baths, exercise, and the other adjuvants must be assiduously employed, and as soon as the effects of the limited diet are clearly marked, opium may be tried. If well borne it should be used determinedly, and pushed to its physiological effects, as indicated by the contracted pupil. If the patient is seen daily his diet should be regulated each day; if only at intervals certain available changes should be indicated. When convalescence begins, and the urine has for some time been free from sugar, the diet may be gradually relaxed, beginning with substances containing little starch or sugar, gradually extending to bread in small quantity; potatoes should come last, sugar itself never. When, with every care, restriction of diet effects no diminution of sugar, or, if that be limited, emaciation and weakness rapidly go on, it will be a question whether it may not be best, as it often is, to return to a practically unrestricted diet.

ALEXANDER SILVER.

DIAGNOSIS of Disease See DISEASE, Diagnosis of.

DIAPHORESIS (διά, through, and *φάω*, I convey).—The act of perspiring. The term is more generally applied to perspiration artificially induced.

DIAPHORETICS (διά, through, and *φάω*, I convey).

DEFINITION.—Remedies which increase the secretion of sweat. When the increase is so great as to cause the perspiration to stand in beads upon the surface, they are usually termed *sudorificæ*.

ENUMERATION.—The principal diaphoretic measures are—The Vapour Bath, Turkish Bath, and Wet Pack; Warm Drinks; Warm Clothing; Jaborandi, Pilocarpin; preparations of Antimony; Ipecacuanha; Opium and Morphia with their preparations; Sarsaparilla, Guaiacum, Serpentry, Sassafras, Senega, Mezereon, Camphor; Sulphur; Ammonia and its Carbonate, Acetate, and Citrate; Alcohol; Ethers (especially Nitrous Ether); and Chloroform.

ACTION.—The secretion of sweat usually consists of two parts, namely, a free supply of blood to the sweat-glands, and the abstraction from it of the materials for sweat by the cells of the gland. These two processes sometimes occur independently of each other. In fevers the supply of blood to the glands is abundant, but they do not secrete; and a similar condition is observed in belladonna-poisoning. Belladonna or atropia possesses the power of paralysing the secreting nerves of the sweat-glands, just as it does those of the salivary glands, and thus the skin remains dry, although the cutaneous vessels are much dilated. In collapse the cutaneous glands secrete a cold sweat profusely, although the supply of blood to them is deficient.

The secreting cells appear to be under the influence of nerves, by exciting which secretion occurs. The centres for the secreting nerves of the sweat-glands appear to be situated in the spinal cord, and in the medulla oblongata. The fibres seem to run in the same path as the vaso-motor nerves. The secretory nerves of the sweat-glands may be excited directly by a stimulation of the nervous trunks in which they run; and the sweat-centres may also be reflexly excited by irritation of various sensory nerves. Certain substances, such as nicotine and carbonic acid, seem to stimulate the sweat-centres; whilst other drugs, such as pilocarpin, appear to act upon the peripheral terminations of the secretory nerves in the sweat-glands themselves. Several remedies, at the same time that they excite secretion, likewise increase the flow of blood through the skin, rendering it redder, warmer, and more vascular. Others, again, excite the secretion at the same time that they diminish the cutaneous circulation. Diaphoretics have therefore been divided into two classes, the former kind being termed *stimulant*, and the latter *sedative* diaphoretics. The exact mode in which each drug already enumerated produces diaphoresis has not yet been ascertained, but antimony, ipecacuanha, and jaborandi are classed as sedative diaphoretics, and all the others as stimulating ones. The supply of blood and the secretion are both increased by the application of warmth, by the ingestion of warm fluids, and by the action of jaborandi.

Uses.—Diaphoretics are employed to increase the flow of blood to the surface, and possibly to aid the elimination of excrementitious products in internal congestion, such as catarrh of the respiratory passages or digestive tract, and in febrile conditions generally. In fevers, the cutaneous circulation is generally active, and the so-called sedative diaphoretics are then most useful. Diaphoretics are also used to increase the elimination of water by the skin, and thus lessen the accumulation of fluid in

dropsy, or to relieve other excreting organs, such as the kidneys in albuminuria and diabetes insipidus, or the intestines in diarrhoea. In these cases stimulant diaphoretics are indicated.

T. LAUDER BRUNTON.

DIAPHRAGM, Diseases of.—The diaphragm may itself be the seat of *functional disturbance*, or of *organic lesions*; or it may be affected by *neighbouring morbid conditions*. For practical purposes its affections may be conveniently discussed according to the following arrangement:—

1. MECHANICAL INTERFERENCE.

2. FUNCTIONAL DISORDERS. (a) Paralysis. (b) Spasm.

3. ORGANIC LESIONS. (a) Injuries, including Ruptures and Perforations. (b) Inflammation, acute or chronic. (c) Muscular Rheumatism. (d) Atrophy and Degeneration. (e) Morbid formations.

1. MECHANICAL INTERFERENCE.—The diaphragm is frequently interfered with by morbid conditions within the chest or abdomen, which impede its action, displace it more or less, either upwards or downwards, or render it tense and stretched. The entire structure may be thus affected, or only a portion of it, such as one lateral half or its central part. The chief thoracic conditions by which the diaphragm may be thus affected are pleuritic effusion or pneumothorax, emphysema of the lungs, abundant pericardial effusion, enlargements of the heart, and tumours within the chest. The principal abdominal conditions deserving notice as being liable to produce this effect are a distended stomach, tympanites, ascites, peritonitis, pregnancy, large fecal accumulations, and tumours or enlarged organs which attain considerable dimensions, especially ovarian, hepatic, splenic or renal tumours. It sometimes happens that the diaphragm is interfered with both from its thoracic and its abdominal aspects.

The symptoms induced by this mechanical interference are readily explained by its effects. A sense of uneasiness and discomfort is often experienced around the lower part of the chest, amounting sometimes to considerable tension and tightness. There is not any actual pain, but in some instances, where the diaphragm is much pushed down, the patient complains of a painful sensation referred to the ensiform cartilage, as if the attachment of the diaphragm at this point were being severely dragged upon. The act of respiration is more or less impeded, and this often seems to be the cause of the discomfort experienced. A sensation frequently complained of by patients is that they cannot take a full breath. Respiration may be much hurried, or oppressed and laboured, and not uncommonly the normal relation between the thoracic and abdominal movements is markedly altered, as observed on physical examination, and the diaphragm may so act as to draw in the lower part of the chest-walls in inspiration. Occasionally a kind of spasmodic cough seems to be excited by the tension of the diaphragm produced by certain conditions. The act of coughing is also frequently rendered more or less ineffectual and ineffectual.

2. **FUNCTIONAL DISORDERS.**—The affections of the diaphragm included within this group are (a) Paralysis; (b) Spasm.

a. **Paralysis.**—The diaphragm is completely paralysed when the upper part of the spinal cord is destroyed, whether as the result of injury or disease. If one or both phrenic nerves should be cut across, or destroyed by disease, or even severely compressed, the same effect will be produced, either one lateral half or the whole of the diaphragm being paralysed, according as one or both nerves are involved. This structure may also be implicated in the course of diphtheritic paralysis.

Where paralysis of the whole diaphragm is suddenly produced, death speedily ensues from the grave impediment to the respiratory function resulting therefrom. If it is brought about gradually, or if only part of the structure is involved, the effects are seen in more or less interference with this function, and with the acts in which respiration is concerned. Thus there will be a subjective sensation of dyspnoea, and of a want of power to breathe; while the respiratory movements will be hurried, shallow, and superior-thoracic. Coughing cannot be performed efficiently, and sputa cannot be expelled, while the abdominal acts for which a tense diaphragm is required, such as defecation or vomiting, are also ineffectual or impracticable. The lower parts of the lungs become more and more congested, fluids accumulate in the air-tubes and pulmonary vesicles, which become by degrees filled up, and the patient ultimately dies of asphyxia.

b. **Spasm.**—The diaphragm may be the seat either of clonic or tonic spasm or cramp. The disorder may depend upon disease of the nerve-centre at the origin of the phrenic nerves; irritation of these nerves in their course; direct excitation of the diaphragm; or reflex causes. Tonic spasm is most strikingly observed in cases of tetanus; of poisoning by strychnia, or of hydrophobia; but a form of asthmatic attack has also been attributed to this condition of the diaphragm.

The symptoms will vary in different cases. Tonic contraction of the diaphragm gives rise to severe pain, and a sense of constriction in the corresponding region, which may come on in paroxysms; clonic spasms also originate painful sensations after a time, which may become very considerable. Hiccup is probably due mainly to a clonic spasm of the diaphragm. If this structure should become rigidly fixed, respiration is gravely interfered with, and the patient soon presents the phenomena of suffocation, which will end fatally if the spasm is not relieved. In the form of asthma supposed to be due to diaphragmatic spasm, expiration is very difficult and greatly prolonged, inspiration being short and abrupt; the lungs are distended; great distress is felt; and there may be signs of impending death from suffocation. A spasmodic cough may be due to clonic spasm of the diaphragm.

3. **ORGANIC LESIONS.**—These may be briefly considered in the order in which they were enumerated at the commencement of this article.

1. **Tubercular Perforation and Rupture.**—

The diaphragm may be perforated, lacerated, or ruptured in connection with various forms of injury, such as crushing accidents, fractured ribs, penetrating wounds, or gun-shot injuries. Should the patient recover, a permanent perforation may be left. In medical practice perforation of this structure may be met with as a congenital condition; as the result of the bursting of some fluid-collection through it, such as an empyema, a hepatic, renal, or other abscess, or a hydatid-cyst; or from its destruction in the progress of some organic lesion, such as malignant disease or an aneurism. It may occasionally occur, independently of these causes, owing to the yielding of a weak portion of the diaphragm, especially between the attachment to the ensiform cartilage and the seventh rib. In rare instances the perforation is congenital, or a considerable portion of the diaphragm may be deficient. The size and other characters of the perforation differ much in different cases. If it is produced by the opening through the diaphragm of a fluid-accumulation, this fluid escapes from the abdominal into the thoracic cavity, or *vice versa*; in other instances the portions of the thoracic or abdominal organs pass through the perforation, constituting forms of *diaphragmatic hernia*. The writer had the opportunity of observing a remarkable instance in which the entire stomach had passed through an opening in the diaphragm into the cavity of the chest. In a case reported by Dr. Little, of Dublin, the diaphragm presented an almost circular opening, well-defined, sharp, with somewhat thick edges, and through this opening passed a hernia consisting of peritoneum containing some omentum, and about fifteen inches of the transverse and descending colon.

To recognise clinically a perforation or rupture of the diaphragm is generally no easy matter. Often there are no symptoms referable to this structure, though there may be signs indicating that its functions are more or less impeded. The occurrence of sudden perforation may be known from the previous existence of some condition likely to cause this event, such as empyema, or an abdominal abscess; the supervention of acute pain, accompanied with indications of shock or collapse, and the disappearance of the signs of the original morbid condition; and followed by the development of phenomena revealing that fluid has passed through the diaphragm, and accumulated in the thoracic or abdominal cavity, as the case may be, or that some secondary affection has been set up as the result of the perforation, such as peritonitis or pleurisy. A fluid collection may, however, penetrate the diaphragm without giving rise to any very evident disturbance. When an organ passes through the diaphragm, the symptoms present, if any, are more likely to be associated with this organ than with the diaphragm, and physical examination may possibly detect the displacement. In the case of hernia of the stomach, already referred to, the chief symptom was vomiting, which occurred immediately after taking any food or drink.

2. **Inflammation.**—The serous covering of the diaphragm, either on its thoracic or abdominal aspect, is not uncommonly involved in cases

of acute pleurisy or peritonitis respectively, and the inflammatory process may penetrate its structure. It may also be involved by extension from pericarditis. Inflammation of the substance of the diaphragm may further arise from injury, direct irritation, pyæmia, or without any evident cause. The anatomical conditions observed are increased vascularity; the formation of lymph upon its surfaces; softening and degeneration of its muscular tissue; or, in rare instances, suppuration, an abscess forming in the substance of the diaphragm, or pus collecting under one or other of its serous coverings. Chronic inflammation of the diaphragm may occur, leading to a fibroid change in its muscular portions, either by extension from neighbouring structures, or as the result of chronic local irritation.

The symptoms of acute inflammation of the diaphragm are generally very obscure and ill-defined. The condition may be indicated by severe pain in the region of this structure, obviously increased by breathing, so that the respiration becomes instinctively thoracic, as well as hurried and shallow; and also much aggravated by coughing, defæcation, or any other act which disturbs the diaphragm. The patient will probably be much distressed. More or less pyrexia will probably be observed. If an abscess should form, this might burst either into the chest or abdomen, and thus lead to secondary pleurisy or peritonitis. Chronic inflammation and its consequences may possibly be suspected from a want of free movement in the diaphragm, associated with conditions likely to originate this change; but it could scarcely be recognised with any certainty.

c. **Muscular Rheumatism.**—The diaphragm may be involved in this complaint, whatever its nature may be; probably it is attended with structural changes in its tissues. The affection is characterised by pain referred to the diaphragm, which may be very acute when it is in any way brought into play. So long as it is kept at rest, there may be no discomfort, but deep breathing causes considerable pain, so that the respiration is carried on in a shallow manner, and may be entirely thoracic. Such acts as coughing or defæcation cause much pain and a sense of aching.

d. **Atrophy and Degeneration.**—The diaphragm may be involved in the course of progressive muscular atrophy; it may also be atrophied from causes which produce general wasting; or undergo senile atrophy and degeneration; or be similarly affected from local causes, such as interference with its blood-supply from vascular degeneration, want of action, or after chronic inflammation. These conditions might give rise to more or less evident interference with the functions of the diaphragm, which in extreme cases would amount to their total cessation, diaphragmatic breathing being rendered impossible, the symptoms being then the same as when the diaphragm is paralysed. In cases of progressive muscular atrophy the fatal termination may arise from this cause. There would not be any pain, but uncomfortable sensations might arise from the impeded respiration.

e. **Morbid Formations.**—The diaphragm is occasionally the seat of malignant disease, being

usually involved by extension from some neighbouring structure. Non-malignant solid growths have in rare instances been found in it. Fungoid formations may also occur in it, namely, *hydatids*, *cysticercus*, and *trichina spiralis*. *Tubercles* are occasionally found in the diaphragm. Possibly malignant disease might be indicated by signs of impeded diaphragmatic movements, with localised pain, accompanying indications of cancer in other parts. The implication of the diaphragm in trichinosis may also be recognised in some instances by severe pains, spasmodic contractions, and serious interference with diaphragmatic respiration. In most cases, however, the presence of any morbid growth in connection with the diaphragm cannot be diagnosed during life, and is only discovered at the post-mortem examination.

TREATMENT.—But little can be done in most cases in the way of direct treatment in connection with affections of the diaphragm. The most obvious indication is to get rid, if possible, of any condition which is mechanically impeding its movements, and preventing it from performing its functions. In the next place, any disease of which the condition of the diaphragm is but a part must receive due attention, such as progressive muscular atrophy, centric nervous disease, or trichinosis. Painful affections might be relieved by local applications of dry heat, fomentations, or anodynes; and if acute inflammation is suspected, a few leeches might be applied. Electricity might prove of service in the treatment of some cases of spasm or paralysis of the diaphragm, the continuous current in the one case, the interrupted current in the other.

FREDERICK T. ROBERTS.

DIARRHŒA (*diapheo*, I flow away).—
SYNON.: *Defluxio*; *Alui Fluxus*; *Purgio*; Fr. *Cours de Ventre*; *Dévoement*; Ger. *Der Durchfall*; *Bauchfluss*; *Durchlauf*.

DEFINITION.—A frequent and profuse discharge of loose or of fluid *alvine evacuations*, without tenesmus.

ÆTIOLOGY.—The causes *predisposing* to diarrhœa are individual *peculiarities*; childhood—especially the period of first dentition; the climacteric period; and hereditary or acquired weakness of the digestive organs.—The *exciting* causes may be thus classified:—1. *Direct irritation of the intestines* by (a) *Food* in excess, or of improper quality—for example, salted meat, shell-fish, sour unripe fruit and vegetables—diseased, decomposed, or imperfectly masticated; the products of faulty digestion prematurely passing the pylorus; imperfectly elaborated and fermenting chyme; impure water, such as that containing from 3 to 10 grains of putrescent animal matter per gallon (Parkes); or imperfectly fermented malt liquors. (b) *Purgative medicines* and *irritant poisons*. (c) *Bile*, excessive or acrid. (d) *Fæces*, retained. (e) *Enteroæa*—lumbriæ, tænia, trichinae, and *entophyta*—mycosis enteralis (Buhl and others). (f) The contents of a ruptured abscess or hydatid cyst. (g) *Intestinal lesion*—such as tubercular or other ulceration. 2. *Defective hygiene*.—Diarrhœa may arise from the dwelling being damp, cold, dark, and unventilated; or from foul emanations from decomposing

organic, especially animal matter, sewage, or faecal collections. 3. *Chills, climatic variations, &c.* Diarrhœa has been attributed to insufficient clothing; sudden exposure to cold and damp; chills, as from wet feet, and damp bed or clothing; over-heating, as by excess of bed-clothing; and rapid variations of temperature, such as hot days and cold nights. 4. *Nervous disturbances*, for example, depressing emotions—fright, grief; neuralgia, hepatalgia (Trousseau), dentition, and other causes of reflex disorder. 5. *Defective absorption with augmented peristalsis*, so that the food is passed unaltered—*Lienteric diarrhœa*. 6. *Symptomatic* in various morbid states, for instance, in passive congestion of the portal vein from disease of the liver, heart, or lungs; peritonitis, especially puerperal; organic disease of the intestines—ulceration (simple, typhoid, tubercular, cancerous), lardaceous degeneration, enteritis, acute or chronic; cholera; typhoid fever; dysentery; occasionally in pyæmia, measles, scarlatina, confluent small-pox, malaria, gout, Bright's disease (its later stages), and in anemia and exhaustion, as from over-lactation, phthisis, cancer, Addison's disease, Hodgkin's disease, exophthalmic goitre, leucocythæmia, and other affections.

Frequently diarrhœa arises from the combined action of several exciting causes, as when the disease is epidemic during summer and autumn. Foul emanations from decomposing organic matter, over-crowding, food (and especially fruit) in a state of incipient decay, excessive heat, and chills, may then collectively determine the result. In children the exalted irritability of the nervous system during dentition predisposes to diarrhœa from slight determining causes.

DESCRIPTION AND VARIETIES.—Diarrhœa may be broadly divided into the *acute* or occasional, and the *chronic* forms; and the numerous clinical and pathological peculiarities of different causes are conveniently grouped into typical varieties. The general effects, varying according to the intensity and duration of the flux, are mainly these:—Emaciation, and, in children, also arrest of growth—the weight either diminishing or ceasing to be progressive; anemia, indicating defective hæmatisation; desiccation of the tissues from the rapid draining of serum from the blood—hence the thirst, and the very concentrated, acid, and even albuminous urine observed when there is a copious watery outflow from the bowels, as in choleraic and similar forms of diarrhœa.

It will be expedient to describe briefly the principal forms of diarrhœa.

1. **Irritative Diarrhœa.**—**SYNON.**: *Diarrhœa Crapulosa* (Cullen).—Simple flux from direct irritation of the intestines is the most common variety of diarrhœa. The evacuations, usually preceded by severe griping pains, are at first feculent and usually fetid and sour, then watery. In children (especially hand-fed) they are often like pale clay or putty, or they contain dense masses of undigested casein before being loose; after evacuation they frequently become greenish, like chopped spinach, from contact with very concentrated acid urine converting the brown coloring matter of the bile into green biliverdin; or they are dark green when passed, and may be used as to excoriate the anus, the genitals,

the inner parts of the thighs, and even the heels. Fever is usually absent.

Diarrhœa from irritation is frequently a preliminary stage of the inflammatory, dysenteric and choleraic varieties.

2. **Inflammatory Diarrhœa.**—**SYNON.**: *Diarrhœa Serosa*.—When the causes of simple irritation excite inflammation of the mucous membrane of the bowels, fever sets in, and the diarrhœa increases. Usually the evacuations become more serous, and contain shreds of fibrin or mucus or pus. Before the attack passes off the large bowels are apt to be the main seat of inflammation; then the motions are scanty, frequent, more mucous or glairy, contain streaks of blood and are passed with severe straining, while the skin is hot and dry.

3. **Choleraform Diarrhœa.**—**SYNON.**: *Choleraic diarrhœa*; *Thermo diarrhœa*—prevails mostly in hot weather. The onset, indicated by vomiting and purging, is usually sudden. At first the vomited matters are mucous and bile-tinted, and the dejections are feculent—both quickly, however, becoming more and more abundant, watery, and colourless. The copious and incessant outflow of serum may in a short time, and especially in children, induce a striking resemblance to the symptoms of Asiatic cholera—a drawn, sunken, and cyanotic appearance, loss of temperature, scanty secretion of urine, insatiable thirst, and cramps; even in extreme cases the fluids from the stomach and bowels are, however, rarely free from bile, and are not so like rice-water as in true cholera. The collapsed algid condition as a rule rapidly gives place to recovery in previously healthy adults, while it is fatal in delicate children, children prematurely weaned, the debilitated, and the aged. Rarely, the cold stage being outlived, the patient becomes hot, and passes into a state of stupor, with either bilious vomiting or purging and tympanites—the typhoid stage. In children death is almost invariable if the cold stage exceeds twenty-four hours.

4. **Nervous Diarrhœa.**—The peristaltic movements, and the activity of the glands of the alimentary canal, are often increased by causes operating through the nervous system. Diarrhœa from mental, and especially emotional, perturbation, is the most common example. Even a chronic looseness may be maintained by debility of the nervous system, induced by worry and anxiety. Exalted innervation of the bowels may be natural, a proneness to diarrhœa from slight exciting causes having always existed; or acquired, when, for instance, a flux once established is apt to be maintained. The unstable nervous system of the periods of rapid development and of the climacteric change predisposes to it. It is often an important factor in chronic diarrhœa. The intestinal nerve-centres may become so sensitive (as in delicate children) that every meal, however small, may induce an immediate call to stool, the motions being liquid or pulaceous, and pale, but otherwise healthy. The peristaltic movements may be even so increased as to hurry the food through the stomach and bowels, so that it appears unchanged in the stools. Time is not allowed for digestion or absorption to be even begun. This form has

been termed *Diarrhœa lenterica*, and is most frequent in children before the period of the second dentition. The increased tonicities of the muscular fibres of the alimentary tract may have resulted from previous inflammation of the mucous surface, or is the propagation upwards of some irritation (ulcer, inflammation, &c.) of the mucous membrane of the rectum; or it arises from the products of imperfect primary digestion entering the duodenum. In adults indigestion is the usual cause. The appetite is as a rule voracious, and debility may become extreme. In painful or difficult dentition, diarrhœa arises from irritation of the nerves of the stomach and bowels; digestion is arrested, and the contents of the alimentary canal become acid from fermentation, and are ejected by vomiting and purging.

5. **Vicarious Diarrhœa.**—Embarrassment or suppression of the functions of the skin, kidneys, or lungs may be met by the bowels performing additional excretory work. The flux thus set up is salutary, because it is compensatory. Diarrhœa from chills (suppressed perspiration) is a common instance, while that from renal and pulmonary causes is less frequently observed, and may be misconstrued by the practitioner. Inasmuch as diarrhœa usually diminishes the quantity of urine, even sometimes to the verge of suppression, the reverse of this clinical fact may be easily overlooked or misinterpreted. Even when forewarned, the observer may at times—especially when the urine is free from albumen—find it difficult to determine whether the diarrhœa is a cause or an effect of imperfect renal elimination—a distinction having all-important bearings on the treatment. The uræmic and eliminatory character of it may be easily decided when the kidneys are known to be diseased; not so, however, when the only thing ascertainable is scanty—maybe albuminous—urine, or total suppression of urine in an elderly patient. In such a case there may or may not be organic disease of the kidneys, and still the diarrhœa may be uræmic, inasmuch as it may depend on ‘renal inadequacy.’ Diarrhœa from pulmonary embarrassment generally affords relief to breathing and cough. The chronic looseness of some gouty patients is also eliminatory: when checked, gout is apt to advance and the health to suffer.

6. **Diarrhœa from mechanical congestion.**—Draining of serum into the bowels is a common result of overloading of the portal vein from an impediment to the flow of blood, either in the vein itself, the vena cava, or the right side of the heart.

7. **Chronic Diarrhœa.** *SYNON.: Curcheetic diarrhœa.*—Chronic diarrhœa is frequently, if not generally, unconnected with intestinal lesions; it may be maintained by chronic catarrh of the intestines, or by an exhausted and impoverished state of the system, as in inanition, either from insufficiency of food or from enfeebled digestion, or in chronic wasting diseases, such as syphilis, malaria, or scurvy. The flux increasing, the debility on which it depends thereby perpetuates itself, and this vicious circle tends more and more to destroy life by anæmia and exhaustion, and even after apparent recovery there is a strong dis-

position to revert to it. These clinical features of chronic diarrhœa are well illustrated by the malady which, from the paleness of the stools, is commonly known in India as ‘White Flux’—a result of deterioration of health by climate and malaria. When accompanied by fever and night-sweats, chronic diarrhœa is nearly always due to tubercularisation.

DIAGNOSIS.—The different forms of diarrhœa may be readily distinguished from each other by a careful consideration of the causes and symptoms. The diseases most apt to be mistaken for diarrhœa are epidemic cholera, dysentery, and mucous irritation of the bowels from retention of feces.

a. *Cholera*, in its less definite forms, may resemble bilious diarrhœa and choleric diarrhœa. The probability in favour of it may be determined by the absence of the ordinary causes of diarrhœa, the paleness and watery character of the stools, tormina being slight or absent, the suppression of urine, and the early exhaustion. The presence of bile in the stools is always in favour of diarrhœa. Vomiting is more frequent in cholera; when it occurs in diarrhœa the vomited matter usually contains bile and undigested food, while in cholera it is a colourless fluid.

b. *Dysentery* is usually characterised by fever, tormina, and tenesmus, and frequent scanty muco-sanguinolent evacuations. Sometimes, however, in the early stage, the motions are copious, watery, and feculent, as in ordinary diarrhœa; but the presence of tormina and tenesmus, and tenderness in the regions of the cæcum and sigmoid flexure, indicate the dysenteric nature of the disease. Chronic diarrhœa may be distinguished from chronic dysentery by the absence of a history of acute dysentery, or of mucus and tenesmus, and the less frequent discharge of blood in the evacuations.

c. *Mucous irritation of the bowels.*—Retention of feces may induce a condition resembling diarrhœa—frequent thin muco-feculent evacuations, which are, however, shown on enquiry to be somewhat scanty, and voided with straining.

TREATMENT.—(a) *Diet and hygiene.* In acute or occasional attacks of diarrhœa, everything should be taken in small quantity, and tepid or cold, never hot. Farinacea—arrowroot, sago, rice, tapioca, flour, and the like are useful, and may be taken in milk, or in chicken or mutton broth, or weak beef-tea. Animal broths—and especially beef-tea—when concentrated, or in large quantity, are apt to aggravate diarrhœa. Mucilaginous drinks—white of egg in water or milk, rice or barley or arrowroot water; and astringent liquids—infusion of dried whortleberries or roasted acorns, red light wines—may be given. Brandy is often of service, and may be mixed with spices or with the farinacea. Lime-water with milk is in many cases of much value.

Rest in bed secures a uniform warmth of skin, and favours the cessation of diarrhœa.

In children, errors of feeding should be corrected. Lumps of casein in the motions may be met by reducing the quantity of milk, and regulating the time between meals, providing a wet nurse, or substituting the milk of the goat or ass for that of the cow. Sometimes, however, milk in any form must be given up. The ab-

muscles should be protected by a flannel bandage, and the feet and legs by warm clothing.

As much as in chronic diarrhœa the flux is potentiated by the debility and anæmia which it induces, and by the activity of intestinal digestion, it has become a leading principle of treatment to prescribe food rich in materials for the construction of the blood and the tissues, and almost wholly disposed of by the stomach. Hence the happy results frequently observed from a diet exclusively animal, either raw or lightly-cooked, the digestion of which may be aided by hydrochloric acid alone or with pepsin. Individual peculiarity may be gratified, and variety obtained from the use of mutton, veal, chicken, pigeon, and game. Beef, the tough parts of veal, and pork are, as a rule, to be avoided. Milk and farinacea are gradually permitted during the progress towards recovery, but the period during which they should be interdicted may require to be very prolonged—even months. The treatment by *raw meat*, strongly advocated by Trousseau and Niemeyer, has been successfully applied to nearly every variety of chronic diarrhœa, but especially to that obstinate one occurring from the time of weaning to the close of the first dentition. The meat may be pounded into a pulp or finely minced, then mixed with salt, sugar, fruit jelly, or conserve of roses, or diffused through clear gravy soup or chocolate made with water or wine; or the juice may be extracted from it by pressure. Notwithstanding the prohibition of other food, it is best to begin with a small quantity, and to increase it gradually. The only drink allowable is water containing white of egg. Trousseau found opium in small doses, chalk, and bismuth, at and between meals, to assist this regimen. When a restricted animal diet cannot be digested, causes *loathing*, or aggravates the flux, other varieties of food may be added, and the feeding should be as generous and varied as possible, and adapted to the digestion of the individual. Articles of diet appearing undigested in the motions should be avoided. Low and damp situations should be exchanged for dry and open ones. Warm clothing, flannel next the skin, and flannel waist-belts should be worn.

(b) *Medicinal Treatment.*—The kind and degree of interference required should first be decided in each case of diarrhœa. A routine prescription of astringents is much to be deprecated. When the flux is moderate and salutary—for example, removing undigested or indigestible materials or irritating secretions, relieving an engorged portal vein, or supplementing a suppressed secretion—it may be left uncontrolled by medicine, or may be encouraged by laxatives, such as castor oil, rhubarb, or a saline aperient, combined with a mild sedative—for instance, henbane or opium: it cannot be checked without risk. As a rule, the treatment of diarrhœa should begin by removing irritating substances from the alimentary canal by aperients guarded by small doses of opium; and astringents, such as chalk-mixture with kino, catechu, hæmatoxylin, and opium, should be held in reserve. A purgative may increase the flux, which, however, soon subsides. Trousseau advocated the use of salines—sodæ sulphas,

sodæ tartarata, magnesie sulphas—in progressively decreasing doses, dissolved in a small bulk of water, in the morning fasting, while others prefer castor oil, rhubarb, or other aperients. Castor oil is by far the most useful remedy for children, as well as for adults; for the former it should be emulsified in gum and syrup, and for the latter in yolk of egg, and as occasion requires combined with a small opiate, for example, compound tincture of camphor, vinum opii, or tincture of opium.

In *choleraic diarrhœa*, the best results are obtained from castor-oil guarded by a small dose of laudanum at the commencement, and repeated if the disease is severe; while astringents and opiates alone are withheld until the bowels are relieved of offensive materials, as in the later stages, the stools being copious and watery, griping and distension of the abdomen absent, and the tongue clean. Vomiting should be encouraged by copious draughts of warm water, and, if need be, by emetics of mustard or ipecacuanha. In children, when the motions are colourless, profuse, and incessant, it is best to give hydrargyrum cum cretâ in small doses every hour or two, and a very small enema of starch, containing phumbi acetos or cupri sulphas, with laudanum, which may be repeated if necessary; and the urgency of the case may likewise demand a firm astringent, such as logwood. In the cold stage there have been recommended mustard baths (for twelve or fifteen minutes, several times a day); emetics (ipecacuanha 2 to 3 grains twice or three times in twenty-four hours); diffusible stimulants (ether in syrup every hour or half-hour); and mercurials (hydrargyrum cum cretâ), in the stage of reaction, saline aperients or calomel in small doses throughout, white-of-egg in water as a drink; and, vomiting having ceased and diarrhœa being established, bismuth, chalk, and lime water.

In *nervous diarrhœa* the first indication is to allay reflex excitability by the bromides, or, these failing, by opium. When diarrhœa is excited by food, the dose should be given shortly before meals. In *lentulo diarrhœa* arsenic is invaluable. Mal-digestion should be met by hydrochloric acid, bismuth with alkalies, or other appropriate remedies, according to the indications. Occasional doses of castor-oil—alone, or with bismuth or small doses of opium or henbane—are useful in clearing away fermentescible matters, which are apt to maintain an irritable state of the bowels. Astringents should only be prescribed after the failure of these or similar measures.

In *vicarious diarrhœa* the skin should be made to act freely by warm baths, or hot air or vapour baths. In renal inadequacy counter-irritation across the loins, digitalis, and nitrate of potash may be likewise indicated. The diarrhœa should not be arrested or even checked unless it be profuse and exhausting, especially after restoring or augmenting the action of the skin and the kidneys; it is sometimes advisable to nurse and encourage it.

Diarrhœa from passive congestion of the portal vein is to be met by treating the cause, for example, disease of the heart, by digitalis, iron, and other remedies.

The flux of *chronic diarrhœa* cannot as a rule be stopped altogether by astringents only—the evacuations while thus retained may decompose, and induce flatulence and colic, or fever. The general health should be restored and *anæmia* removed; the secretions will then generally improve and the diarrhœa subside. Tonics—iron, arsenic, quinine, strychnia—may be aided by astringents—mineral acids, opium, bismuth, chalk, or hæmatoxylium. The best preparations of iron are iron alum—3 to 5 grains, and liquor ferri perigratus—10 to 40 minims. Ipecacuanha and taraxacum are useful when the skin and liver are inactive: from 1 to 3 grains of pulvis ipecacuanhæ may be given night and morning. Podoophyllum—2 or 3 minims of a solution of 1 grain in 1 drachm of rectified spirit three or four times a day—is indicated when the motions are watery, pale or high-coloured, and passed with severe cutting pains. Saline purgatives in the early morning are recommended—2 drachms of sulphate of soda, sulphate of magnesia, or soda tartarata on the first day, then 1 drachm for fourteen days, dissolved in a small bulk of water, with avoidance of fluids after the dose—and from 1 to 2 grains of rhubarb, also taken fasting. The profuse sweating and colliquative diarrhœa of hectic is best met by hæmatoxylium and dilute sulphuric acid, or opium with astringent mineral salts—nitrate of silver, sulphate of copper, or acetate of lead—by the mouth or rectum.

Suppressed secretions, particular cachexiæ, disturbed innervation, congestion of the portal vein, and organic diseases of the intestines, form special indications for treatment when diarrhœa is present.

GEORGE OLIVER.

DIATHESIS (*διαθήκη*, I dispose).—A morbid constitution, predisposing to the development of a particular disease. See CONSTITUTION, with which, in a somewhat more limited sense, this term is synonymous.

DIATHETIC DISEASES—Constitutional diseases. See CONSTITUTIONAL DISEASES.

DICROTISM (*δίσ, double, and κρότος, a stroke*) is a term applied to the second great wave of the pulse. This dicrotic wave of dicrotism is due to a second expansion of the artery which occurs during the diastole of the ventricle. The *pulsus bis forens* of old authors was a pulse in which a second beat became perceptible to the finger; an occurrence observed occasionally as an antecedent of hæmorrhage and also in the course of fevers. The second beat perceived by the finger is not always the true dicrotic wave, but may in some cases be an exaggerated tidal wave. This is the wave perceived in the high arterial tension sometimes antecedent to hæmorrhage. The mode of production of dicrotism is not quite agreed on; it is favoured by a low state of arterial tension, by elasticity of the arterial coats, and by quick and strong ventricular contractions. It is generally considered to be central in its origin, and to be a wave of recoil from the closed aortic valves reinforced by an oscillation set up in the aorta. The other view refers the origin of the dicrotic wave to the periphery. The wave of

blood discharged at each ventricular systole is, in consequence of its acquired velocity, disturbed from its state of equilibrium; and, as a result of the resistance offered by the peripheral vessels, reflows towards the heart, whence it is again reflected. See PULSE.

BALTHAZAR FOSTER.

DIET.—**DEFINITION.**—Diet may be defined as expressing the regulation of food to the requirements of health and the treatment of disease.

GENERAL PRINCIPLES.—In order to sustain life, a diet must consist of a proper apportionment of the following alimentary principles:—

1. Nitrogenous principles.
2. Non-nitrogenous principles (fats, carbohydrates, &c.)
3. Inorganic materials (saline matters and water).

Whilst these principles hold different relative positions of value, the absence or deficiency of either group will render a diet unfit for the support of life. Milk, the product provided by Nature as the sole article of sustenance during the early period of the life of mammals, may be regarded as furnishing us with a typical dietetic representative of all these principles. The egg also holds a like position, and, as all the parts of the young animal are evolved from it, must needs comprise all the materials for the development and growth of the body.

The required principles are contained in food derived from both the animal and vegetable kingdoms, and the diet may be drawn from either, but, looking to man's general inclination and the conformation of his digestive apparatus, it may be assumed that a mixed diet is that which is designed in the plan of Nature for his subsistence, and it is that upon which he attains the highest state of physical development and intellectual vigour.

Animal food, being identical in composition with the body to be nourished by it, is in a state to be more easily appropriated than vegetable food. It also appeases hunger more thoroughly and satisfies longer: in other words it gives, as general experience will confirm, greater stay to the stomach. Animal food possesses stimulant properties which have sufficed in certain instances, as after starvation, and in those accustomed to a vegetable diet, to produce a state allied to intoxication. This stimulating effect is further illustrated by looking at the relative character of animal and vegetable feeders. Liebig says that it is essentially their food which makes carnivorous animals in general bolder and more combative than the herbivora which are their prey. He then relates that a bear kept at the Anatomical Museum of Gießen showed a quiet gentle nature as long as it was fed upon bread, but a few days' feeding on meat made it vicious and dangerous.

The standard diet framed by Moleschott has been accepted as furnishing a model of what may be considered the requisite proportion of alimentary principles for maintaining health in a person of average stature under exposure to a temperate climate and a moderate amount of muscular work. It runs as follows:—

Alimentary substances in a dry state required daily.

Dry Food	In ounces avoird.
Albuminous matter . . .	4.587
Fatty matter . . .	2.954
Carbo-hydrates . . .	14.250
Salts . . .	1.058
	<hr/> 22.859 <hr/>

This, it will be seen, furnishes a supply of about 23 ounces of dry solid matter, and of this one-fifth is nitrogenous. If we reckon that ordinary food contains about 50 per cent. of water, then 23 ounces will correspond to 46 ounces of solid food in the condition in which it is consumed. To complete the alimentary ingesta, a further quantity of from 50 ounces to 80 ounces of water may be assumed to be required to be taken daily under some form or other.

For a life of inactivity, it must be stated that a much smaller amount of food will suffice. The diet, for instance, which is ordinarily supplied to the patients of Guy's Hospital, and which suffices to satisfy and properly sustain them, only contains about 30 ounces of solid food, equivalent to about 17 ounces of water-free material.

It has been mentioned that there are reasons for regarding a mixed diet of animal and vegetable food as best adapted to our nature, and it may probably be considered that the most suitable admixture contains about one-fourth or rather more of animal food.

Looked at from the following point of view, it will be seen that an admixture of animal and vegetable food more economically supplies what is wanted, than either kind taken alone, unless the adjustment should be made with the proper apportionment of fat as a representative of a non-nitrogenous article. It is estimated that for a man of medium stature, and performing a moderate amount of work, about 300 grains of nitrogen and 4,800 grains of carbon are daily required to be introduced into the system with the food, to compensate for the outgoing of these elements that occurs. Now this is yielded, as nearly as possible, in the case of both elements, by 2 lbs. of bread and $\frac{3}{4}$ lb. of meat—that is, 44 oz. of solid food, of which about one-fourth consists of animal matter. If the lean of meat only were consumed, rather over 6 lbs. would be needed to furnish the requisite amount of carbon, and there would be a very large surplus of unutilisable nitrogen; whilst if bread only were taken, the amount necessary to supply the requisite quantity of nitrogen would be rather more than 4 lbs., and this contains nearly double the amount of carbon wanted.

In order to preserve health it is necessary that a portion of the food consumed should be in the fresh state, and this applies to both animal and vegetable food. There may be no lack of quantity, and yet disease and death may be induced by inattention to this fact. Affections of the scorbutic class are produced, which can only be checked and removed by the supply of fresh food or the juice of some kind of succulent vegetable or fruit. The efficacy of lemon and lime juice, for instance, is well known in the prevention and cure of scurvy.

Climate influences the demand for food, and instinct leads to the adaptation of diet to the requirements that exist. Not only is there a correspondence between the amount of food required and the inclination for taking it, but the nature of the food selected in different countries varies and stands in harmony with that which is most in conformity with what is needed. The dwellers in the arctic regions, besides consuming a large quantity of food, partake of that kind which abounds in the most efficient form of heat-generating material, namely, oleaginous matter. In the tropics, on the other hand, it is upon vegetable products, largely charged with principles belonging to the carbo-hydrate group, that the native inhabitants mainly subsist.

Labour necessitates a supply of food in proportion to the amount of work done. The employer finds that the appetite of a workman may be taken as a measure of capacity for work—in other words, that a falling off of the appetite means a diminished capacity for the performance of labour.

Until recently, it was considered, in accordance with the teaching of Liebig, that muscular and nervous action resulted from an oxidation of muscular and nervous tissue, and that according to the amount of action occurring, so was a demand for the supply of nitrogenous alimentary principles created to replace the oxidised material. It is now held, however, that the non-nitrogenous elements of food contribute, as well as the nitrogenous, to the production of muscular and nervous force. Fick and Wislizenus undertook a known amount of work upon a non-nitrogenous diet, and proved that the oxidation of their muscular tissue, as measured by the amount of nitrogen voided with the urine, sufficed only for the production of a small proportion of the force expended in the accomplishment of the work performed. The muscles, in reality, appear to stand in the position of instruments for effecting the conversion of the chemical energy evolved by the oxidation of combustible matter into working power. Fats and carbo-hydrates can furnish the combustible matter required, and, under ordinary circumstances, probably do largely, if not chiefly, supply it. Nitrogenous matter can do so likewise, but it has to undergo a preparatory metamorphosis for effecting the separation of nitrogen in a suitable form for elimination. It must be said, however, that experience shows that hard work is best performed under a liberal supply of nitrogen-containing food. The explanation of this probably is that it leads to a better-nourished condition of the muscles and of the body generally. Under the use, for instance, of animal food, which is characterised by its richness in nitrogenous matter, the muscles are observed to be firmer and richer in solid constituents than under subsistence upon vegetable food.

Persons who lead a sedentary and in-door life naturally require less food than those engaged in active work, and less should be consumed by them to prevent the system becoming clogged with effete products, which act perniciously in various ways upon the body. The food should also be largely constituted of non-nitrogenous principles, as these tax the excretory organs less than the nitrogenous.

The diet of *infants* is a branch of dietetics the importance of which can scarcely be over-rated. The proper food during the first period of infancy is that which has been provided by Nature for the young of mammals, namely, milk. Up to about the eighth month the infant is designed to be sustained solely by its parent's milk. The teeth, which ordinarily begin to show themselves about this time, indicate that some solid matter should now be consumed, and ~~one~~ of the farinaceous products will be the most suitable with which to commence. Bread, baked flour, plain biscuit, or ~~one~~ of the numerous kinds of nursery biscuits that are made, may be employed for a time as a supplement to the former food. At about the tenth month the mother, who ought previously to have commenced lessening her own supply, should now cease it altogether. As the child advances through its second year and the teeth become more developed, meat, preceded for awhile by gravy, may be given. If the mother cannot suckle her child, or a wet nurse, whose supply stands next best to that of the mother, be provided, the milk of one of the lower animals should be obtained, and that of the cow gives the nearest approach to what is wanted. Cow's milk, however, is richer in all its solid constituent principles than woman's, and the addition of a solution of sugar or—what is more in conformity with the natural supply—sugar of milk (lactine), in the proportion of an ounce to three quarters of a pint, is needed to bring the two in closer approximation. The milk of the goat is even richer in solid constituents than that of the cow, and therefore stands somewhat further removed from that of the human subject. If, however, it is not adapted for infants, it is highly useful for improving the condition of badly-nourished children, and is sometimes employed for this purpose.

THERAPEUTICAL APPLICATIONS.—The application of the principles of dietetics may be successfully brought to bear in the treatment of corpulency and thinness. A diet rich in nitrogenous matter conjoined with exercise promotes the growth of muscle, but the fat undergoes no increase. The conditions most conducive to an increased accumulation of fat are a diet rich in either fat or carbo-hydrates (provided the requisite amount of nitrogenous matter be present for affording what is wanted for the nutritive operations of life), exposure to a warm atmosphere, and inactive habits. A supply of fat in a direct manner, leads to an increased deposition of fat in the system, but the carbo-hydrates require in the first place to undergo assimilative change before they can be applied in the same direction.

The details of the dietary to be prescribed where the aim is to produce increased stoutness and an improved condition of the body, should comprise such articles as fat meats, butter, cream, milk, cocoa, chocolate, bread, potatoes, farinaceous and flour puddings, oatmeal porridge, sugar and sweets, sweet wines, porter, stout, and ale.

The converse mode of dieting is necessary for reducing stoutness. Mr. Banting, by his noted system of dieting, reduced his weight from 14 stone 6 lbs. to 11 stone 2 lbs. in about a year. Besides altering, however, the character

of his food, he limited the quantity in a manner that must have contributed an important share towards producing the effect observed; not more than twenty-two to twenty-six ounces of solid food (corresponding with eleven to thirteen ounces of water-free material) being consumed, according to his statement, in the twenty-four hours.

As a guide to the corpulent it may be said that the fat of meat, butter, cream, sugar and sweets, pastry, puddings, farinaceous articles as rice, sago, tapioca, &c., potatoes, carrots, parsnips, beetroot, sweet ales, porter, stout, port wine, and all sweet wines should be avoided, or only very sparingly consumed. Wheaten bread should only be partaken of moderately, and brown bread is to some extent better than white. The gluten biscuits which are prepared for the diabetic may, on account of their comparative freedom from starch, be advantageously used as a substitute for bread in the treatment of obesity. The articles that may be taken to the extent of satisfying a natural appetite, are lean meat, poultry, game, eggs, green vegetables, succulent fruits, light wines, dry sherry, and spirits. Milk should only be taken sparingly.

Holding the position that food does in relation to the operations of life, the art of dietetics not only bears on the maintenance of health but is capable of being turned to advantageous account as a therapeutic agency; and it is not too much to say that success in the treatment of disease is oftentimes dependent upon a display of judicious management in regard to food.

In the therapeutic application of dietetics the maxim should be held in view that, whilst the particular requirements are secured, there should otherwise be no greater deviation from what is natural than the special circumstances of the case demand.

The quantity of food consumed may require to be regulated as well as its nature. The quantity administered at a time should stand in relation to the power of digesting it; and to properly compensate for a diminished capacity for taking quantity there should be a corresponding increase in the frequency of administration. 'Little and often' is the maxim to be followed upon many occasions, and much will sometimes depend upon the strictness with which it is acted up to; for, apart from harmonizing with what is wanted, upon the principle that has just been referred to, it meets the defective aptitude that exists in sickness for sustaining any lengthened duration of abstinence from food.

In febrile, acute inflammatory, and other conditions where there is a failure of digestive power, the food administered should be such as not to tax the stomach, and should therefore consist of liquid materials. Solid matter, by remaining undigested—and solids of an animal nature are particularly likely to do so—would act as a source of irritation in the stomach, and only serve to aggravate the condition of the patient. The articles under such circumstances to be selected from are beef-tea, mutton, veal, or chicken broth, whey, calf's-foot and other kinds of jelly, arrowroot and such-like farinaceous articles; barley water, rice mucilage, gum-water, fruit jelly, and the juice of fruits, as of lemon,

oranges, &c., made into drinks. Where a little latitude is allowable, the employment of milk and of eggs in a fluid form may be sanctioned. As circumstances permit, an advance may be made to solid substances which do not throw much work on the stomach, as rice, sago, tapioca, bread and custard puddings, and stale bread or 'crust supped. Next may be allowed fish, beginning with whiting. As power becomes restored, calves' feet, chicken, game, and butcher's meat—mutton to begin with—may be permitted to follow.

In cases of ordinary dyspepsia the aim of the physician should be rather directed to raising, by appropriate treatment, the digestive capacity to the level of digesting light but ordinary food, than to reducing the food to an adjustment with a low standard of digestive power. Of butcher's meat, mutton is almost invariably found to be the most suitable; chicken and game are allowable, also white fish (boiled or broiled) particularly whiting, sole, flounder, and plaice. Stale bread, dry toast, plain biscuits, floury potatoes, rice, and the various farinaceous articles form the kind of food derived from the vegetable kingdom to be selected. Green and other succulent vegetables, it is found, are more apt to create flatulence than other kinds of food, and articles belonging to the cabbage tribe are particularly to be regarded as obnoxious to those who have a tendency to this form of derangement.

Much depends in cases of weak digestion upon the state in which the food reaches the stomach. Thorough mastication affords great assistance to the performance of digestion, and when the teeth are bad the food should be finely minced, or otherwise minutely divided before being eaten. Regularity in the periods of taking food, tends to promote the orderly working of the digestive organs. An interval of more than four or five hours' duration between the meals is to be avoided, as it acts perniciously in several ways. By inducing an exhausted state of the system it diminishes the energy of the digestive organs, and whilst having this effect it at the same time calls for the periodical exercise of increased energy, on account of the larger amount of food which must be taken at each meal to compensate for the length of time that is allowed to elapse between them.

In cases of ulcer of the stomach, acute gastric catarrh, and vomiting, the food must be selected from that which is nutritious and at the same time taxes least the digestive power. Milk—and this is often better borne after being boiled—milk and water, or milk and soda water, will frequently be found to be tolerated when other articles excite irritation and are returned. Sometimes the milk may be advantageously mixed with isinglass, arrowroot, ground rice, or biscuit powder.

In dysentery and other forms of ulcerative disease of the intestine, scrupulous attention must be paid to diet. The food should consist of articles which are known to exert the least stimulant and irritant action on the mucous membrane and muscular coat of the alimentary canal, and those which best meet the demand in question are such as milk, isinglass, and the various farinaceous products, amongst which rice is pre-

ferred. White fish, white-fleshed poultry, fresh game, and fresh meat. Salted and dried meats are highly objectionable, and fruits and succulent vegetables, with the exception of a floury potato, should be strictly shunned. See PEPYSSIAN FOOD.

The development of gout is known to be favoured by the consumption of a highly nitrogenised diet, especially if conjoined with sedentary habits. With those who have already experienced symptoms of the disease, and those also who have grounds for apprehending its invasion, it is important that an excess of nitrogenous food should be avoided. The diet should be simple, in order that the temptation may be avoided of eating too much, and should at the same time be adjusted to the mode of life. The principle to observe is that the higher the degree of inactivity the greater ought to be the preponderance of food derived from the vegetable kingdom.

Even of more importance than what is eaten is what is drunk, where the question of gout is concerned, and observation shows that it is not distilled spirits, but the stronger wines and malt liquors, which favour the production of the disorder. Nothing is more potent than port wine in leading to the production of gout, and a few years' liberal indulgence in it has often been known to be instrumental in bringing on the disease where no family predisposition had existed. Dry sherry and the light wines, as claret, hock, &c., may be drunk, certainly in moderation, with comparatively little or no fear of inducing the disease, although any kind of wine appears capable of sometimes acting as the exciting cause of a paroxysm where the gouty disposition is already established. Stout, porter, and the stronger ales, especially those that have become hard from age, rank next to port wine in their power of predisposing to gout. As regards the light bitter beers, which are so extensively used at the present time, the same must be said of them as of the light wines, viz. that with little, if any, disposition to induce the disease, they nevertheless appear capable of sometimes exciting its manifestation in a gouty subject. A pure spirit, as whisky, hollands, or brandy, diluted with water, often forms the only kind of alcoholic drink that is found to agree with those who are suffering from gout.

In Bright's disease with threatening uræmic poisoning it is a point of consideration to diminish as far as practicable the amount of excretory matter to be eliminated by the kidney. The fats and carbo-hydrates throw no work upon the kidneys. Their products of destruction escape through another channel. Nitrogenous matters, on the other hand, undergo metamorphosis in the system, and yield nitrogen-containing compounds—chiefly urea—to escape by the kidneys. In this way the kidneys become taxed by nitrogenous food, and, to lessen the work demanded of them, reason suggests that the diet should preponderate in food derived from the vegetable kingdom.

In diabetes mellitus there is a want of assimilative power over the saccharine and starchy principles of food. Whilst these principles become utilized and lost sight of when ingested by a healthy person, in the system of the diabetic they fail to become consumed, but pass off under

the form of sugar in the urine, giving rise to severity of symptoms in proportion to the amount of sugar escaping. Much may be done towards subduing the symptoms of the disease by a properly arranged dietetic scheme, and the principle upon which it requires to be framed is the exclusion, as far as practicable, both from what is eaten and what is drunk, of articles containing saccharine or starchy matters.

Observation has shown that the reaction of the urine is susceptible of being influenced by the character of the food. The effect of animal food is to increase the acidity of the secretion, whilst that of vegetable food is to diminish it, and, even it may be, to produce alkalinity. Hence on persons affected with the lactic acid diathesis benefit is conferred by a plan of diet in which animal food is limited, and succulent vegetables and fruits, with the light wines, as claret, hock, &c., are freely supplied. On the other hand, with the phosphatic diathesis, the converse principle of action should be adopted.

F. W. PAYR.

DIGESTION, Disorders of.—The function of digestion is of a physico-chemical nature, being compounded of certain muscular acts, and of certain processes exercised by the digestive fluids on the ingesta.

Any interference with the due performance of the several components of the function will lead to indigestion, and though it may for convenience be desirable to consider these disturbances separately, it must be remembered that the occurrence of one condition is apt to be quickly associated with another, and hence the forms of dyspepsia as they usually present themselves are of a complex nature, however simple the primary fault may have been. Nor is it possible to consider irregularities of digestion only from the point of view of the organs immediately concerned. Complicated as our organism is, disturbances of other functions will speedily make themselves felt in the one under consideration, and failures in the absorption of the digested food, or in its subsequent metabolic changes and elimination, will tell back sooner or later on that process which is, strictly speaking, limited to its preparation. Dyspepsia then may be traced to (i.) the food; (ii.) disturbances of the so-called mechanical processes, viz. the muscular acts, solution, &c.; or (iii.) imperfections in the chemical changes exercised by the digestive secretions.

I. IMPERFECTIONS OF FOOD.—Imperfections in food, whether in quality or quantity, are among the most frequent causes of digestive disorders. A thorough knowledge of the principles of dietetics is essential, that the errors may be recognised and remedied. Since our digestive capability is limited, it is obvious that when those limits are overstepped, the domain of disease is entered upon; and although no very absolute lines may be laid down for universal application, the general rules for quantity and kind are capable of being stated. See DIET.

Even when the food is as it should be, dyspepsia may be determined by perversions of the appetite; or, on the contrary, such perversions may be due to the same causes which lead to the

functional errors in the digestive organs. See APPETITE.

(a) Deficiency of Food.—Except under rare conditions, such as famine, &c., this is not so common a cause of disease as is supposed. We habitually take a larger bulk of food than is demanded, and it is very certain that most active lives are led on an amount of food far below what is ordinarily regarded as being necessary. May it not be that many of the diseases looked upon as non-preventible, more particularly those connected with the excretory organs, are really due to their overwork in getting rid of the excess of the ingesta? Of the signs and symptoms of starvation it is not needed here to treat. But there are frequent occasions when, with no deficiency in the total bulk of food taken, there is yet a serious want in one or perhaps more of the needful alimentary principles, and this is especially liable to occur in the feeding of children. Setting aside those gross cases of cruelty, when infants and the youngest children are fed almost from their birth with bread, broth, or even meat, there are still too often to be met with children whose diet-scale is almost entirely wanting in nitrogenous matter. Fed upon milk and infants' foods, the latter consisting of little more than starchy material, their tissues are ill-formed for the want of proteids, which, during the period of growth, are required in a larger relative proportion. The relationship of rickets to prolonged suckling, with the accompanying deficiency in nitrogenous and amyloid food-stuffs, is now generally recognised.

The effect of a deficiency of food is a general state of malnutrition, in which any hereditary tendencies to disease that may exist have a more favourable field for development. There is a gradual diminution in the weight of the body, and an imperfect performance of its functions, as indicated by muscular weakness, mental lassitude, &c.

The deficiency in food taken may result not so much from a defective supply of nutriment, as from a disinclination to eat, a common symptom in most diseases, especially in febrile states, self-imposed fasting too frequent or prolonged, the anorexia of the hysterical temperament, and obstruction to the entrance of food into the stomach from stricture of the œsophagus, or the appetite may be impaired by over-indulgence in alcohol or tobacco.

(B) Excess of Food.—There is very little doubt but that more food is daily in the habit of being taken than is actually required to restore the tissue-waste, as there is equally little doubt that much of what is taken is not in the most digestible form. It is open to question whether the appetite would be satisfied by the ingestion of merely sufficient to balance the waste, particularly if the gross bulk of the food taken were diminished by the removal, as far as possible, of all indigestible matters, leaving little more than the needful alimentary principles. At the same time it must not be forgotten that the appetite is very easily controlled by custom, and determination can in time overcome a vicious habit.

An habitual excess of food, at least in this

summary, usually errs in the disproportionate amount of nitrogenous matter it contains. Remembering the relatively small quantity of this principle that is essential, and in what a number of the ordinary articles of diet it is contained, this statement will be the more readily accepted. Now, since all the proteid principles require, to fit them for absorption into the blood, a considerable amount of chemical alteration, and, physiologically speaking, there is good reason to believe that the subsequent metabolic changes of these matters, when absorbed, are more complex than those undergone by fats and amyloids, it would follow that those organs concerned in effecting these changes are very prone to suffer from overwork and its sequelae. Again, it appears very probable that when the amount of nitrogenous food taken is much in excess of what is required, it undergoes certain oxidation-changes in the blood without becoming tissue previously, and an enormous ingestion of albuminoid matter is followed by its elimination very much as it is taken. Now, many of the compounds resulting from the oxidation of nitrogenous matter are liable to become positive poisons in the economy when existing in excess, and the proper elimination of such materials is specially provided for by such organs as the kidneys and skin. The frequency with which these organs become the seat of disease may at least indicate the probability of errors of diet being an important factor in determining the morbid changes, especially as considerable relief is often the result of a restriction of nitrogenous food. There can be little doubt but that the large group of diseases associated with failure in elimination of nitrogenous waste has for a prominent cause an habitual excess of nitrogenous food.

The results of an excessive ingestion of food are as numerous as they are diverse. In many cases there does not seem to be either impairment of health or shortening of life. In some obesity and in others leanness ensues. In a large majority of individuals whose food is much in excess of their wants, particularly if the exercise taken be but little, there are variable symptoms of indigestion, such as a general feeling of lassitude and want of energy, both muscular and mental, a liability to headaches chiefly frontal, constipation, or more rarely diarrhoea, high-coloured urine depositing abundance of urates, a general disposition to sleep, various skin-eruptions, particularly acne, and not infrequently a feeble heart's action from commencing fatty degeneration of its substance. Any or all of these symptoms may exist, and may be more or less completely relieved by a restricted diet. It is impossible to lay down any exact rules for the quantity of food that should be daily consumed; though it is desirable to remember that the tendency is to take too much, at the same time that age, season of year, and occupation are all circumstances determining variations both in quantity and kind.

(7). *Improper Food.*—Setting aside those extreme cases of perverted appetite occasionally seen in the hysterical condition, there yet remains a very constant violation of the dietetic proprieties. These errors may be classed under

the following heads:—1. Substances which are indigestible; either essentially so, or from imperfect preparation (cooking, &c.) 2 Substances which, though digestible, are unnutritious or even poisonous. In the first group are included such bodies as the pips and seeds as well as the skins and rinds of fruits, the husks of corn and bran, the stalks and fibres of leaves, and gristle, elastic tissue, and hairs in animal food. For the reducing of these to a fluid and diffusible condition no chemical arrangement exists in the human organism, and they are thrown off very much in the same state as they are swallowed. Many articles of diet depend in great part for their digestibility on their proper preparation by division, cooking, &c. Thus most vegetables when taken in the raw state are but imperfectly digested, and such nutritious food as potatoes becomes when uncooked positively harmful. The apparent value of raw green vegetables, as lettuce, endive, cress, &c., would seem to depend on the peculiar condition of their mineral constituents, rather than on the vegetable tissues.

Such substances as the above-mentioned are apt to produce perversions of digestion in virtue of the mechanical irritation they give rise to, indicated by more or less pain of a gripping character (colic), and frequently accompanied by diarrhoea. The constant ingestion of the more formidable may even set up a gastro-enteritis, acute or chronic. Occasionally articles of food, such as brown bread, oatmeal porridge, &c., are taken for the very aperient action they induce, owing to the irritating nature of the indigestible husks they contain. Symptoms of acute dyspepsia very frequently follow the taking of meat foods enveloped in greasy sauces, since the fat, being undigested in the stomach, prevents the action of the gastric juice on the proteid matter, which then passes on into the intestines, setting up irritation like any other indigestible substance. The most interesting among these articles of diet which, though easily digested may be poisonous, are those producing their effects only on certain individuals. Such, for example, are certain mushrooms, shell-fish, or indeed any fish. Remarkable cases are authentically recorded of serious and even fatal results following their ingestion. The symptoms may be those of an acute gastro-enteritis, or, as is very frequently the case, an urticaria is the result, with or without swelling of the eyes and throat. Severe nervous prostration has been met with occasionally. Be it understood that other people have partaken of the same diet with no ill results. The writer is acquainted with a gentleman who for many years was unable to remain in the room when fish of any kind was on the table; its presence inducing severe vomiting, abdominal pain, and general illness; and although the effects are now but slight from the mere smell of such food, very marked symptoms follow on partaking of any. The most digestible and nutritious articles of food may determine indigestion when taken too hot or too cold.

Finally must be included those substances which accidentally find their way into the alimentary canal with the food, as entozoa, ergot of rye; such foreign bodies as pins, needles,

caine, buttons, &c.; or lead and other metallic poisons off the hands of workers in these poisons; all of which give rise to definite and for the most part characteristic symptoms.

II. IRREGULARITIES OF THE MECHANISM OF DIGESTION.—The motor factors of the digestive process depend for their due and normal performance on the integrity of the muscular tissue, the nerve-centres, and the connecting nerves. The several stages of the entire process are mastication, deglutition, the churning movements of the stomach, the peristaltic action of the intestines, and defecation. Each of these is liable to impairment, in the direction of excess (spasm), or of deficiency (paralysis), due either to lesions of the nerve-centres whence the motor stimuli emanate, of the nerve-fibres by which these stimuli are conveyed, or of the muscular tissue by which the movements are performed. Not unfrequently more than one of these tissues may be at fault. Lastly, obstructions to the movements may be caused by tumours, cicatrices, &c. Irregularities of mastication, deglutition, and defecation are fully considered elsewhere.

1. Paralysis.—Arrest of the peristaltic action of the gullet, stomach, or intestines is undoubtedly often associated with diseased conditions of the central nervous organs, but the exact connection is far from being satisfactorily known. Those lesions which interfere with the action of the vagus nerve, and remove its accelerating influence over the peristaltic movements, have been regarded as most likely to bring about this condition. The nervous exhaustion induced by long fasting, continued vomiting, hysteria, and such diseases as typhus and puerperal fever, have been noticed as removing the influence of the pneumogastric. Over-brainwork, with the attendant altered conditions of cerebral vascularity, have been found to be accompanied with symptoms indicating loss of power of the muscular coat of the bowel; possibly in this case also the influence is conveyed by the vagus.

Paralysis of the stomach and intestines is a frequent result of affection of these organs themselves. Inflammation of the peritoneal or mucous coats, with the subsequent infiltration of the muscular coat with the inflammatory products, materially diminishes the power of the contractile tissue. Degeneration of the organs, particularly the lardaceous variety, which commencing in the mucous subsequently invades the muscular coat, obviously interferes with the movements. The movements of the alimentary canal may be considerably diminished by the administration of certain drugs, such as opium.

The results of these various paralytic affections are in most cases sufficiently apparent. The palsied lips and cheeks and tongue tell their own tale by the half-opened mouth, the dribbling saliva, and the cheeks distended with food which cannot be kept between the teeth. When the fauces and pharynx are affected, the painful efforts at swallowing, the rejection of food through the nose, and the passage of food into the larynx are signs not to be mistaken. Paralysis of the stomach and intestines is mainly recognised by the constipation from inability of the canal to propel its contents, and by the distension with gases, &c., which ensues: whilst the

involuntary passing of the flatus indicates paralysis of the sphincter ani.

2. Spasm.—Spasmodic affections of the alimentary canal are characterised by an increased motor activity dependent on many causes for its production. However diverse such causes may be, they ultimately resolve themselves either into an increased irritability of the nervous and contractile tissues, or into some unusual or excessive stimulation, arising *ab extra*, and so producing its motor result in a reflex manner, or originating automatically in the cells of the motor ganglia. Spasms affecting the organs under consideration are determined both by central and peripheral causes, and occasionally by affections of the nerves independently of the nerve-centres. They are mainly of the tonic variety, and are usually accompanied by pain.

It is clear that with the muscular tissue of the alimentary canal arranged as it is, when a condition of spasm exists obstruction to the passage of the contents of the canal will take place, in proportion to the extent and duration of the cramp.

Spasm of the stomach and intestines is almost invariably accompanied by pain; and it is for that symptom, rather than for any obstruction, that the condition comes under notice. The pain at the back, so frequently complained of in anæmia, is believed to be mainly due to gastric spasm; and in certain other constitutional states, such as gout, it may be a prominent symptom. Occasionally it is due to uterine or ovarian disturbances, acting in a reflex manner. Spasm of the pylorus is of theoretic rather than practical interest. Intestinal cramp (colic, tormina, &c.) is of frequent occurrence as the result of irritating ingesta, lead-poisoning, hernia, intussusception, and ulceration in malignant disease. These spasmodic affections may also result from diseases of the spinal cord. How far over-action of the involuntary muscular tissue of the alimentary tract may exist without pain is uncertain; since we are ordinarily unconscious of the peristalsis, it is probable that any exaggeration of action is painful.

The normal tenacity of the sphincter ani may give place to painful spasm, a condition which is very apt to complicate fissure and ulcer of the anus.

Hyperkinesia, or exalted motor activity of the muscular tissue of the digestive organs, may be a part of the general state induced by such poisons as strychnine.

3. The due performance of the mechanism of digestion may be interfered with by alterations in the condition of the alimentary canal caused by various kinds of obstruction or dilatation. Thus deglutition may be rendered difficult or even impossible by a swollen tongue or tonsils, post-pharyngeal abscess, tumours of the œsophagus or larynx, or new growths situated at the cardiac aperture of the stomach. The various obstructive diseases of the pylorus and intestines will obviously interfere with the proper passage of the contents, and in those dilations of the canal, which are liable to develop above a stricture, the food accumulates and is delayed in its passage. The adhesion of coils of the bowels to each other or to adjacent structures is a further source of imperfect movement.

the absorption of the solid food, so that the efficiency of the digestive process is materially undermined when the alimentary canal is diseased or is overworked, and the cause of the dyspepsia is a mass of dyspeptic food to be daily eliminated.

It is essential to a knowledge of the mechanism of digestion as vomiting is more fully described by itself, though it is a very frequent symptom of indigestion.

III. KNOWLEDGE OF THE CHEMICAL CHANGES.—Our knowledge of the normal chemistry of digestion, such as it has advanced of late, is still very far from complete, and, in face of our ignorance, but little can be said of the conditions existing in disease. Yet there are certainly no departures from the healthy working of the body so common as are those associated with the digestion of the food.

The various secretions, whose office it is to convert into a fluid and diffusible form those alimentary principles which without such preparation cannot be absorbed, are formed from the blood by the salivary, gastric, pancreatic, hepatic, and intestinal glands. It is clear that, for these juices to be secreted in proper quantity or of proper composition, the blood no less than the secreting cells must be in a healthy condition. If the circulating fluid be laden with imperfectly secreted products of tissue-change, or if it be charged with poison, of whatever origin, it is not to be expected that a normal secretion is to be obtained from it; whilst on the other hand a degenerated secreting epithelium is unable to perform a function intimately dependent on the integrity of its protoplasm. Of necessity these two factors—blood and cells—react on one another; any flaw in the one is reciprocated by the other, and thus becomes intensified by mutual interdependence. Experiment leads us to ascribe the efficacy of these juices in the changes they effect to the existence in them of certain so-called ferments, whilst the result they bring about is mainly one of hydration. How far the various mineral constituents of the secretions aid in the process is uncertain, but at least their presence cannot be dispensed with. In this way, the insoluble starches of our food are converted by the saliva, the pancreatic, and possibly the intestinal juices, into soluble and diffusible sugars; the various proteids are rendered capable of absorption into the blood, by the gastric and pancreatic juices, and perhaps also the viscous enterics, being changed into bodies known as peptones. The fats are prepared for absorption by the bile and pancreatic juice, by being in part reduced to a sufficiently minute state of subdivision (emulsion) to permit of their passage through the tissue-interstices, and partly by being chemically altered into soaps. How accurately we may imitate the separate actions of these fluids in our test-tubes and laboratories, and how far they are undoubtedly much more complex in the alimentary canal, where so many other processes are going on, and so many sets of

conditions the multifarious symptoms which such changes undoubtedly give rise to.

Primarily the secretions may be deficient in quantity, improper in quality, or both, and the following are some of the causes leading to such results:—

1. *Perverted nervous influence.* The direct control of the nervous system over the quantity and quality of the secretions is well known, and there is every reason to suppose that the temporary arrest of the salivary fluid so frequently accompanying any severe mental disturbance, such as fright, represents, but in a transitory manner, a disturbance that may be more lasting and more serious in lesions of the central nervous organs. The imperfect digestion, as indicated by the tongue, breath, excreta, &c., so common in brain-diseases, even when all precautions are taken, is only to be explained in this way. There is nothing improbable in suggesting that a cause which may in one case bring about an arrest of secretion, may, if prolonged, induce a perversion of the same.

2. *Abnormal blood-supply.* A deficiency in blood being almost always associated with an alteration in its quality, it is easy to see why, in a state of anemia the digestive function suffers, whilst the more it fails the more will the anemia increase. Hence the care needed both in diet and drugs for such patients. In some cases the blood may be wanting in those constituents which go to form the secretions. Occasionally persons are met with who, from habit or inclination, take a quantity of fluid far below the ordinarily supposed requirements. In such the secretions would seem to be insufficient in quantity to do their work, and an irritable form of dyspepsia, caused by the presence of imperfectly digested food, is the result. Or again, certain symptoms may point to a deficiency in such special elements of the secretions as hydrochloric acid, bicarbonate of potash, &c., and considerable relief or a cure may follow the administration of these substances, or it may be the ferments themselves are wanting, and pepsin or pancreatin are indicated. It is not asserted that our knowledge at present leads us to recognise with accuracy the exact nature of the deficiency in the secretions, but in view of the relief that is afforded by acting on the lines laid down by physiology, it is only reasonable to expect that in time the expressions of disease may be more exactly defined, and so a rational basis constituted for treatment. After prolonged fasting the gastric juice is secreted in but small amount, and under ordinary conditions that which is first poured into the stomach is far less active than that later formed. In other words the quality of the secretion improves as the food, which supplies its ingredients, is absorbed. Hence the occasional advantage of prefacing a meal with a small quantity of some piquant food.

From a blood laden with impurities, whether of ingesta or non-eliminated products of tissue-waste or specific poisons, healthy secretions are not to be expected, even did the secreting agents remain healthy. Thus the dyspeptic symptoms associated with alcoholism, gout, and the acute specific diseases are to be explained.

3. It has already been said that it is practically impossible to dissociate altered blood

From our imperfect knowledge we can yet trace the causes of the abnormal secretions; however far we may be from being able to restore them to their proper con-

DIGESTION. DISORDERS OF.

states from perverted tissue-structure; and if the nutritive fluid of the body be diseased, the elements nourished by it may be expected to be imperfect. Some of these departures from the normal are not recognised, partly from the difficulty of observing them, and still more from ignorance of the exact standard of healthy structure in tissues which are perpetually changing, even within healthy limits. Other changes, however, we can see; and the degenerate cells of an amyloid liver, or the desquamating epithelia of the gastric follicles in scarlatina, can no more be expected to eliminate healthy secretions, than can a fatty heart to contract properly.

A further source of disturbance in the chemical changes in digestion is to be found in the fermentative and putrefactive processes set up in the contents of the alimentary canal. How far such processes are normal is uncertain; but occasionally the contents of the stomach are vomited in a state of active fermentation, and teeming with living organisms. All ill-smelling gases and excreta may be, indeed, indicative of the progress of putrefaction lower down in the canal. That gastric juice and bile will normally arrest putrefaction, whilst pancreatic juice favours it, is well known, and hence we are led to infer some alteration in the secretions when signs of decomposition appear.

SYMPTOMS OF DYSPEPSIA.—The almost numberless symptoms which indicate the perverted functions above described, may be considered as those associated with the special organ at fault; and those manifested by the system generally.

(a) Among the first group are *perverted sensations*. Ordinarily we are unconscious of the process of digestion, but in disease the function may be accompanied by alterations of sensation, varying from a mere sense of weight and discomfort in the abdomen to the severe spasmodic pain of colic. The ingestion of food may be followed by a feeling of abnormal repletion, or of emptiness with craving for food; or there may be heartburn, an ill-defined sense of burning felt in the epigastrium or over the chest, or extending to the throat, or positive pain or tenderness felt over some tolerably definite area. Sensations as of excessive movements of the bowels, of sinking, or of tightness across the abdomen, are of frequent occurrence.

(b) Affections of the *appetite* as results of indigestion have already been referred to.

(c) The various *movements* of the alimentary canal may be interfered with. They may be delayed or even arrested, as occurs in constipation; or excessive, with consequent diarrhoea. Vomiting, either directly or at a variable interval after taking food, is a common symptom, with or without pain; very frequently the vomiting relieves the unpleasant feelings that may be present. Eructations of gas, hicough, and the frequent passing of much flatus occur in many cases.

(d) The *vomited matters* vary considerably. The food may be ejected very much as it has been swallowed, or it may be in a state of active fermentation and turning into ferments. A symptom very often complained of is the eructation into the mouth of a fluid, which is frequently acrid and bitter, at other times tasteless (pyrosis): it is probably altered gastric secretion.

Blood may be vomited, or passed in the stool, per rectum (melaena).

(e) The state of the tongue, and the general appearance of the face, the smoothness, and prominence of the veins, are indicative of the condition of the alimentary intestines.

(f) Such *sympathetic symptoms* as pain in the back or in the right shoulder, head-ache, specks in the field of vision, palpitation, irregular action of the heart, cough, disordered urine, &c., indicate the relation existing between the digestive organs and the body generally.

(g) The more *general symptoms* that are found associated with disordered digestion may be those of pyrexia, when an acute inflammatory condition of the digestive organs is the cause of the disturbance. Since, however, the affections are more usually of a chronic nature, a general wasting and emaciation from insufficient nourishment is likely to ensue. In such a state the patient is prone to develop any diathesis to which he may be liable, such as the neurotic, cancerous, &c. The peculiar sallow, muddy-looking skin, often slightly tinged with bile and markedly anæmic, is characteristic of many cases of chronic indigestion; a poorly nourished body can ill stand the slightest fatigue, though such patients are often apt to brighten up towards evening, and indeed as a rule dyspeptic patients are worse in the morning. All conditions of disordered temperament are met with, from a confirmed apathy and hypochondriasis to a persistent and increasing irritability. Whilst some patients are always drowsy, others complain of a distressing insomnia, or a troubled and dreamy sleep.

TREATMENT.—Often perhaps than may be supposed, the cause of the disturbance of digestion is a removable one; in any case it must be well searched for, and arrested if possible. A carefully regulated diet, both as regards ordinary food and drinks and special idiosyncrasies, is in all cases the most important, and the means from which much good is to be expected. Exercise, bathing, occupation both mental and bodily, change of scene and air, will require attentive consideration. Much, however, may be done with the aid of drugs. Sufficient indications often exist to justify prescribing, with perfect confidence, such tonics as vegetable bitters, quinine, strychnine, and iron; such constituents of the digestive juices as mineral acids, pepsin, and alkalies; or drugs whose value appears mainly to consist in their sedative action, as hydrocyanic acid, bismuth, opium, and belladonna. Arsenic, zinc, silver, creosote, charcoal, valerian, the hypo-sulphites, and the carminatives generally, are a few among the long list whose value is assured in different cases of dyspepsia. It is important to attend to the condition of the bowels; as well as to the hepatic functions. See STOMACH, Diseases of.

CONCLUSION.—In the foregoing remarks an attempt has been made to enter into a detailed description of the various symptoms of disordered digestion, or to do more than indicate verbally the treatment to be followed. Such matters are left to the discretion of the practitioner in the several articles. Nor has it been thought fit in this article to treat the subject of the

Lastly, the subdivision of the solid food, so necessary for the effective action of the digestive juices, is only imperfectly performed when the teeth are deficient in number or are carious, and to this cause a large proportion of cases of dyspepsia may be fairly assigned.

So marked a perversion of the mechanism of digestion as vomiting is more fitly described by itself, though it is a very frequent symptom of indigestion.

III. IMPERFECTIONS IN THE CHEMICAL CHANGES.

—Our knowledge of the normal chemistry of digestion, much as it has advanced of late, is still very far from complete, and, in face of our ignorance, but little can be said of the conditions existing in disease. Yet there are certainly no departures from the healthy working of the body so common as are those associated with the digestion of the food.

The various secretions, whose office it is to convert into a fluid and diffusible form those alimentary principles which without such preparation cannot be absorbed, are formed from the blood by the salivary, gastric, pancreatic, hepatic, and intestinal glands. It is clear that, for these juices to be secreted in proper quantity or of proper composition, the blood no less than the secreting cells must be in a healthy condition. If the circulating fluid be laden with imperfectly secreted products of tissue-change, or if it be charged with poison, of whatever origin, it is not to be expected that a normal secretion is to be obtained from it; whilst on the other hand a degenerated secreting epithelium is unable to perform a function intimately dependent on the integrity of its protoplasm. Of necessity these two factors—blood and cells—react on one another; any flaw in the one is reciprocated by the other, and thus becomes intensified by mutual interdependence. Experiment leads us to ascribe the efficacy of these juices in the changes they effect to the existence in them of certain so-called ferments, whilst the result they bring about is mainly one of hydration. How far the various mineral constituents of the secretions aid in the process is uncertain, but at least their presence cannot be dispensed with. In this way, the insoluble starches of our food are converted by the saliva, the pancreatic, and possibly the intestinal juices, into soluble and diffusible sugars; the various proteids are rendered capable of absorption into the blood, by the gastric and pancreatic juices, and perhaps also the succus entericus, being changed into bodies known as peptones. The fats are prepared for absorption by the bile and pancreatic juice, by being in part reduced to a sufficiently minute state of subdivision (emulsion) to permit of their passage through the tissue-interstices, and partly by being chemically altered into soaps. However closely we may imitate the separate actions of these fluids in our test-tubes and laboratories, the conditions are undoubtedly much more complicated in the alimentary canal, where so many sets of changes are going on, and so many sets of products are formed.

Despite our imperfect knowledge we can yet suggest in outline the causes of the abnormal chemical changes, however far we may be from ascribing with accuracy to their proper con-

ditions the multiform symptoms which such changes undoubtedly give rise to.

Primarily the secretions may be deficient in quantity, improper in quality, or both, and the following are some of the causes leading to such results:—

1. *Perverted nervous influence.* The direct control of the nervous system over the quantity and quality of the secretions is well known, and there is every reason to suppose that the temporary arrest of the salivary fluid so frequently accompanying any severe mental disturbance, such as fright, represents, but in a transitory manner, a disturbance that may be more lasting and more serious in lesions of the central nervous organs. The imperfect digestion, as indicated by the tongue, breath, excreta, &c., so common in brain-diseases, even when all precautions are taken, is only to be explained in this way. There is nothing improbable in suggesting that a cause which may in one case bring about an arrest of secretion, may, if prolonged, induce a perversion of the same.

2. *Abnormal blood-supply.* A deficiency in blood being almost always associated with an alteration in its quality, it is easy to see why in a state of anemia the digestive function suffers, whilst the more it fails the more will the anemia increase. Hence the cure needed both in diet and drugs for such patients. In some cases the blood may be wanting in those constituents which go to form the secretions. Occasionally persons are met with who, from habit or inclination, take a quantity of fluid far below the ordinarily supposed requirements. In such the secretions would seem to be insufficient in quantity to do their work, and an irritable form of dyspepsia, caused by the presence of imperfectly digested food, is the result. Or again, certain symptoms may point to a deficiency in such special elements of the secretions as hydrochloric acid, bicarbonate of potash, &c., and considerable relief or a cure may follow the administration of these substances, or it may be the ferments themselves are wanting, and pepsin or pancreatin are indicated. It is not asserted that our knowledge at present leads us to recognise with accuracy the exact nature of the deficiency in the secretions, but in view of the relief that is afforded by acting on the lines laid down by physiology, it is only reasonable to expect that in time the expressions of disease may be more exactly defined, and so a rational basis constituted for treatment. After prolonged fasting the gastric juice is secreted in but small amount, and under ordinary conditions that which is first poured into the stomach is far less active than that later formed. In other words the quality of the secretion improves as the food, which supplies its ingredients, is absorbed. Hence the occasional advantage of prefaceing a meal with a small quantity of some piquant food.

From a blood laden with impurities, whether of ingesta or non-eliminated products of tissue-waste or specific poisons, healthy secretions are not to be expected, even did the secreting agents remain healthy. Thus the dyspeptic symptoms associated with alcoholism, gout, and the acute specific diseases are to be explained.

3. It has already been said that it is practically impossible to dissociate altered blood

states from perverted tissue-structure; and if the nutritive fluid of the body be diseased, the elements nourished by it may be expected to be imperfect. Some of these departures from the normal are not recognised, partly from the difficulty of observing them, and still more from ignorance of the exact standard of healthy structure in tissues which are perpetually changing, even within healthy limits. Other changes, however, we can see; and the degenerate cells of an amyloid liver or the desquamating epithelia of the gastric follicles in scarlatina, can no more be expected to eliminate healthy secretions, than can a fatty heart to contract properly.

A further source of disturbance in the chemical changes in digestion is to be found in the fermentative and putrefactive processes set up in the contents of the alimentary canal. How far such processes are normal is uncertain; but occasionally the contents of the stomach are vomited in a state of active fermentation, and teeming with living organisms. All ill-smelling gases and excreta may be, indeed, indicative of the progress of putrefaction lower down in the canal. That gastric juice and bile will normally arrest putrefaction, whilst pancreatic juice favours it, is well known, and hence we are led to infer some alteration in the secretions when signs of decomposition appear.

SYMPTOMS OF DYSPEPSIA.—The almost numberless symptoms which indicate the perverted functions above described, may be considered as those associated with the special organ at fault, and those manifested by the system generally.

(a) Among the first group are *perverted sensations*. Ordinarily we are unconscious of the process of digestion, but in disease the function may be accompanied by alterations of sensation, varying from a mere sense of weight and discomfort in the abdomen to the severe spasmodic pain of colic. The ingestion of food may be followed by a feeling of abnormal repletion, or of emptiness with craving for food; or there may be heartburn, an ill-defined sense of burning felt in the epigastrium or over the chest, or extending to the throat, or positive pain or tenderness felt over some tolerably definite area. Sensations of excessive movements of the bowels, of sinking, or of tightness across the abdomen, are of frequent occurrence.

(b) Affections of the *appetite* as results of indigestion have already been referred to.

(c) The various *movements* of the alimentary canal may be interfered with. They may be delayed or even arrested, as occurs in constipation; or excessive, with consequent diarrhoea. Eructations of gas, hicough, and the frequent passing of much flatus occur in many cases.

(d) The *vomited matters* vary considerably. The food may be ejected very much as it has been swallowed, or it may be in a state of active fermentation and turning into ferments. A symptom very often complained of is the eructation into the mouth of a fluid, which is frequently acrid and bitter, at other times tasteless (pyrosis); it is probably altered gastric secretion

Blood may be vomited (hæmatemesis); or passed per rectum (melæna). The breath may be foul.

(e) The state of the *tongue*, its colour, size, and general appearance as to fur, dryness, smoothness, and prominence of papillæ, are often indicative of the condition of the stomach and intestines.

(f) Such *sympathetic* symptoms as headache, pain in the back or in the right shoulder, dimness, specks in the field of vision, palpitation, or irregular action of the heart, cough, disordered urine, &c., indicate the relation existing between the digestive organs and the body generally.

(g) The more *general* symptoms that are found associated with disordered digestion may be those of pyrexia, when an acute inflammatory condition of the digestive organs is the cause of the disturbance. Since, however, the affections are more usually of a chronic nature, a general wasting and emaciation from insufficient nourishment is likely to ensue. In such a state the patient is prone to develop any diathesis to which he may be liable, such as the neurotic, cancerous, &c. The peculiar sallow, muddied-looking skin, often slightly tinged with bile and markedly anæmic, is characteristic of many cases of chronic indigestion; a poorly nourished body can ill stand the slightest fatigue, though such patients are often apt to brighten up towards evening, and indeed as a rule dyspeptic patients are worse in the morning. All conditions of disordered temperament are met with, from a confirmed apathy and hypochondriasis to a persistent and increasing irritability. Whilst some patients are always drowsy, others complain of a distressing insomnia, or a troubled and dreamy sleep.

TRÉATMENT.—Often perhaps than may be supposed, the cause of the disturbance of digestion is a removable one, in any case it must be well searched for, and arrested if possible. A carefully regulated diet, both as regards ordinary food and drinks and special idiosyncrasies, is in all cases the most important, and the means from which much good is to be expected. Exercise, bathing, occupation both mental and bodily, change of scene and air, will require attentive consideration. Much, however, may be done with the aid of drugs. Sufficient indications often exist to justify prescribing, with perfect confidence, such tonics as vegetable bitters, quinine, strychnine, and iron; such constituents of the digestive juices as mineral acids, pepsin, and alkalies; or drugs whose value appears mainly to consist in their sedative action, as hydrocyanic acid, bismuth, opium, and belladonna. Arsenic, zinc, silver, creasote, charcoal, valerian, the hypo-sulphites, and the carminatives generally, are a few among the long list whose value is assured in different cases of dyspepsia. It is important to attend to the condition of the bowels; as well as to the hepatic functions. *See* STOMACH, Diseases of.

CONCLUSION.—In the foregoing remarks no attempt has been made to enter into a detailed description of the various symptoms of disordered digestion, or to do more than indicate very generally the treatment to be followed. Such subjects are left to the diseases treated of in their respective articles. Nor has it been thought desirable in this article to treat the subject from the ill-

defined point of view of 'varieties of dyspepsia.' Rather it has been sought to bring the matter of indigestion within the limits of an anatomico-physiological basis, since it is only on such lines that the protean symptoms of dyspepsia can be accurately defined. At the same time, whilst for clearness the various causes have been made to assume a somewhat tabular form, it is not intended that the interdependence of these states should be overlooked, or that one only of the causes mentioned is at work in any given case. The complexity and harmony of our functions alike forbid such a mistake being made. Yet for that mental analysis which the formation of a diagnosis presupposes, some such scheme as the foregoing is essential, no less than for the adoption of a rational treatment.

W. H. ALLCHIN.

DIGESTIVE ORGANS, Diseases of the.

—The organs comprised in the digestive system have for their function the preparation of the solid and fluid ingesta of the body, so as to fit them for absorption into the blood. Some of the food requires little or even no such preparation; some needs considerable treatment, both physical and chemical. To effect this object it would appear to follow that there should be some receptacle or series of receptacles into which the food may readily be taken, and from which the worthless residue may escape, provided with muscular structures to ensure a movement of its contents. It would further follow that there should be certain organs communicating with the foregoing, whose function it should be to prepare those materials necessary to effect the required chemical changes in the food; and, lastly, that some arrangement should exist to permit of the ready absorption of the digestive materials. Such requirements we find supplied in the alimentary canal, with its terminal apertures, and its continuous muscular coat so arranged as to maintain a progressive advance of the contained food, though with varying degrees of speed—for some lengths, as through the gullet, without any arrest; in others, as in the stomach with considerable delay. Into this canal open numerous glands (mucous, salivary, gastric, intestinal, hepatic, and pancreatic), the secretions of which play each their special part in the conversion of the food to a fluid and diffusible state. From an anatomical, and indeed a genetic point of view, those glands may be regarded as more or less complicated diverticula of the mucous surface. In order that the food when so treated may gain a ready entrance into the blood, the surface of the canal in contact with the digesting food—mucous membrane—offers various modifications—villi, &c.—to facilitate the process of absorption. Lastly, in beings so complex in structure as man, there is need for some controlling influence to bring the operation of this system of organs into harmony with the actions of other and interdependent systems. Such power of co-ordination is exercised *via* the nervous system, sympathetic and cerebro-spinal.

By the expression 'diseases of the digestive organs' is meant, departures from the normal structure of the tissues of which these organs

DIGESTIVE ORGANS, DISEASES OF.

The constructive tissues of the alimentary organs are:—1. The Epithelial, 2. The Connective; 3. The Muscular, and, 4. a compound texture—the Vascular. Each of these is subject to its own perversions, either alone or in common with others.

ETIOLOGY.—If we consider diseases to be altered functions dependent on altered structure, the latter being determined by some perversion in the normal stimuli to nutrition, either hereditary or acquired we shall at once recognise that the opportunities for abnormal stimulation in the case of the digestive organs are most numerous. Communicating with the external world and continuously subject to the admission of foreign matter, we have in the character of the ingesta abundant sources of disease. Toxic agents, living and dead, find ready entrance, and excesses in quantity of food, no less than imperfection in its quality, alike serve to produce those departures from the normal structure on which perversions of function depend.

Furthermore, the tissues of the alimentary viscera are, equally with those of the body generally, subject to those more obscure hereditary influences which determine irregularities in structure and their sequence. And, finally, arrests in development of organs, not unfrequent in those under consideration, complete the list of possible diseases to which the alimentary system is liable.

Nor is this system independent of morbid conditions affecting other organs. So complicated as is the human body it is impossible that disease should for long be limited to one region. Sooner or later the functions which are now reacting the one upon the other, to constitute the harmonious working of healthy life, will feel the effects of the one that is out of gear, and will respond each in its own manner to the abnormal condition. A disease primarily located in the nervous system will produce an effect in the working of the nutritive functions, none the less real because the exact lesion cannot as yet be determined. Failures in elimination of the products of tissue-waste from structural diseases of the excretory glands, must tell back on the organs concerned in the preparation and elaboration of the ingesta, and such conditions constitute a frequent cause of disorders of digestion. The causes may be thus tabulated:—

A. Hereditary.

1. Arrests in development of tissues and organs.
2. Abnormal nutritive stimuli, determining new growths, &c.

B. Acquired.

1. Poisons,
2. Imperfections in quantity or quality of normal ingesta.
3. Failure of excretory functions with consequent circulation of an impure blood, and malnutrition of tissues.
4. Trophic disturbances acting *via* the nervous system.
5. Traumatic.

CLASSIFICATION OF DISEASES.—There is scarcely any form of diseased structure that is not to be met with in the tissues comprising the digestive organs. Since almost every variety of texture is

found in them, and there is so extensive a liability to the causes of disease, this result is only to be expected.

1. Affections of the Vascular State.—Regarded collectively, the organs of digestion present several points in respect to their blood-supply worthy of remark. First, the arrangement of the vessels is such as to ensure a very extensive, and at the same time, very direct supply. The arteries to those alimentary organs situate in the abdomen are almost all primary branches of the aorta, and this, together with the numerous and free anastomosis between them, reduces to a minimum the chance of failure in circulation. Secondly, the blood from the same area is all collected into one large vein, the portal, and after circulating through the liver is carried by one—the hepatic—directly into the inferior vena cava close to the right auricle. Such an arrangement, whilst perhaps facilitating the direct return of blood, offers a double chance—viz., in the liver and in the heart—of producing a very general state of congestion of the alimentary tissue. Thirdly, the existence of such an organ as the spleen, which by its position and structure allows of great variation in the amount of blood it contains, will considerably affect the extent of vascularity of the digestive organs. Our knowledge of the conditions determining the variations in splenic blood-capacity is most imperfect, beyond the fact of the constant enlargement which the organ undergoes after a meal and its subsequent contraction after a few hours, the enlargement being due in great part to increase in the amount of blood contained in it. And, lastly, the alimentary organs probably undergo, within normal physiological limits, a wider variation in amount of blood than does any other system.

1. Hyperæmia is an excess of blood in the arterial side of the capillaries. How far a determination of blood to the alimentary canal may exist, unaccompanied by any change in the tissue, is a matter of doubt. In the normal process of digestion this condition obtains, but with it there is an alteration in the glandular epithelia, if in no other tissue-elements. It is conceivable, however, that a vaso-motor paralysis with consequent fluxion may occur, and such may be the case in certain mental states, as indicated by diarrhœa. The majority of circumstances that produce hyperæmia do not stop at that point, but bring about a state of catarrh and inflammation, in which the epithelial and connective tissues are also engaged. Exposure to cold and extensive superficial burns probably produce their well-known results of intestinal catarrh in this manner.

Among the digestive glands, the liver undoubtedly manifests states of simple hyperæmia without any appreciable changes in the parenchyma of the tissues. Excessive feeding, irritants such as spices and alcohol, hot climates and malaria, have all been recognised as producing temporary enlargements of the liver from vascular engorgement, although without doubt these causes if continued lead to structural affections.

2. Congestion, or an excess of blood primarily in the venous side of the capillaries, brought about by some impediment to the return of the blood

in the veins, has little or no analogy with any normal physiological action. As a condition of disease it is more important and far more common than the preceding.

The two chief causes leading to its occurrence are—(A) Obstruction through the portal circulation in the liver, either by compression of the portal capillaries by cirrhosis, &c., or pressure in the portal trunk by enlarged glands, tumours, &c. (B) as part of a general congestion due to obstruction at the right side of the heart from tricuspid dilatation. Due to the very direct communication of the veins of the chylipoietic viscera and the right auricle, these organs are among the first to experience the effects of the cardiac obstruction. Congestion of the alimentary canal and glands, when due to either of these causes, is in the main progressive in its nature, though occasionally liable to temporary relief from treatment.

Extreme conditions of vascularity, especially if associated with any hæmorrhage into the sub-epithelial tissue, present post-mortem appearances often mistaken for irritant poisons.

3. Results of Increased Vascularity.—(a) *Hæmorrhage.* Over-fulness of the capillaries, from whatever cause, is liable to lead to extravasation of blood, either by diapedesis of the corpuscles and trans-fusion of the fluid part of the blood, or from actual rupture of the vessels. It is much more common and far more extensive in venous congestion than in arterial hyperæmia. It must not be too readily assumed *post mortem* that either of these conditions alone is the cause of the hæmorrhage, since minute ulcers of the mucous membrane communicating with main vessels have been met with. Dependent on the course and situation, the effused blood may vary in colour from bright red to a coffee-ground appearance. Hæmorrhage due to altered states of the blood is of frequent occurrence in purpura, scurvy, &c. (B) *Edema.* An over-distension of the vessels, especially of the veins, if it be at all persistent, is invariably accompanied by an effusion of serum into the substance of the viscera themselves and into the alimentary canal, in the latter case producing diarrhœa. (γ) Tissues the seat of a chronic congestion in time undergo certain structural changes as the result of their impaired nutrition, which are characterised by the presence of an excessive amount of connective tissue, containing fewer protoplasmic elements than normal, and exhibiting a marked tendency to contract. The fibroid substitution may occur throughout the entire digestive system, but is particularly noticeable in the stomach, intestines, liver, and pancreas.

4. Anæmia.—The alimentary viscera, in common with the rest of the body, may share in a general bloodlessness due to excessive loss or extreme malnutrition from wasting disease, &c. A deficiency of blood limited to these organs is not clinically met with.

5. Isærations.—As compared with the brain, spleen, and kidneys, the organs of the alimentary system would appear to be less prone to suffer from emboli and thrombi, or at all events from the effects of their conditions. A partial exception to this general statement must be made in the case of the liver, which is a frequent seat

of abscess determined by the arrest in the portal capillaries of septic particles taken up by the portal radicals in dysentery, &c. Emboli, as a cause of gastric ulcer, are probably not so common as has been supposed by Virchow.

II. Structural Affections.—1. *Inflammation.* This term is applied to express those changes which take place in the nutrition of a tissue subsequent to the application of some abnormal stimulus which shall not have been sufficiently powerful to produce destruction. The changes in the structural elements of the textures result in the production of some material which is unlike the normal constituents of the part affected, and also in certain destructive phenomena. One or other of these aspects may predominate, as in suppuration and abscess or ulceration, &c. Certain variations present themselves in the nature of the new-formed material, and also in the general course of the process, constituting forms of inflammation, as simple, diphtheritic, phlegmonous, aphthous, &c. In vascular tissues there are in addition to the tissue-changes certain variations in the circulation in the affected region, commencing with hyperæmia and leading to a variable amount of stasis.

Inflammation as it affects the alimentary tract offers no exception to this description. The transition, so far as anatomical appearances are concerned, from the normal state of activity of the organs, with their increased vascularity and cloudy appearance of the epithelial cells, to that of simple inflammation or catarrh, is but a step marked by no abrupt line. The entire canal, with the gland-ducts opening into it, may be the seat of various forms of inflammation, some regions being rather more prone than others, as the fauces, stomach, small intestine, and bile-ducts.

It is rare in inflammation of the canal for the muscular tissue to share in the process, which is practically limited to the epithelial and sub-epithelial connective tissue, and a similar condition exists in regard to the ducts of the various glands. It is a noticeable fact that the epithelium of the canal are but little prone to manifest that general suppurative form of inflammation accompanied by a large production of pus from the general surface, such as is so commonly seen in the bronchial, nasal, vaginal, and other mucous membranes. In inflammation of the various glands it would appear that next to the ducts the connective-tissue stroma is mainly the tissue affected, leading to a proliferation of the corpuscles and ultimate formation of a less protoplasmic form of fibrous tissue.

Among the chief results of inflammation are:—

(a) *Abscess.*—This may occur in any part of the submucous tissue, in the so-called phlegmonous and pyæmic inflammation, but is of most common occurrence in the tonsils and in the liver, often in the latter situation the result of inflammation determined by absorption into the mesenteric veins of septic particles from dysenteric ulceration.

(b) *Ulceration.*—The mucous membrane of the alimentary canal is particularly liable to this morbid process. Some preference is exhibited by the different forms of ulcer for certain

the tendency to perforate the entire thickness of the tube, those of shorter duration frequently producing this result, whilst the chronic ulcers are usually accompanied by a slow formation of indurated connective tissue, which proceeds *pari passu* with the destructive process, and is especially likely to institute adhesions between the canal and adjacent organs. Ulcers are met with in the salivary, hepatic, and pancreatic ducts, very frequently as a sequence of inflammation determined by the passage of calculi.

The ulcers which are usually acute in their course are:—1. Simple. 2. Aphthous. These forms, though they may occur in any part of the mucous membrane, are far more commonly situated in the gums, cheeks, tongue and palate. 3. Acute specific ulcerations, as diphtheritic and scarlatinal, mainly affecting the fauces; or typhoid, limited to the jejunum and ileum, and originating in the solitary and agminated glands. 4. Dysenteric.

The ulcers that are commonly chronic in their course are—1. Gastric. 2. Tubercular, which may occur in any part of the canal, but are usually limited to the same situation as the typhoid. 3. Syphilitic, most common in the mouth, fauces, and rectum. 4. Cancerous. 5. Dysenteric.

Ulcers, the result of injury or of corrosive poisons, may be either acute or chronic. The latter are rarely met with below the stomach.

(γ) *Sloughing and Gangrene.*—The inflammatory state may be so intense as to lead to molar death of the area affected, with the production of slough. This often follows scarlatinal inflammation of the fauces, and the surface of the large intestine in dysentery is frequently covered by large and numerous sloughs.

Gangrene is almost entirely limited to the mouth in children, when it produces the condition termed noma. The cheeks are usually affected first, the process rapidly involving the gums, jaws, &c. The cause is very obscure.

Post-mortem softening and destruction of the stomach and intestines is frequently met with, and is due to an actual digestion of the viscera by the gastric juice, which, thus escaping from the stomach, may cause destruction of adjacent organs. It is usually met with when death has occurred during the process of gastric digestion, and is more common in infants, possibly from the greater acidity of the products of digestion (lactic acid).

2. *Hypertrophy.*—A general overgrowth of the normal tissues of the digestive organs is practically unknown. Certain parts may manifest this condition, notably the muscular tissue of parts of the canal above an obstruction. The liver is described as being occasionally hypertrophied in certain cases of diabetes.

3. *Atrophy.*—The alimentary organs may share in the general atrophy and wasting of old age or inanition. This condition is apt to follow the disease of certain parts, as is seen in the thinning and shrinking of the stomach and intestines beyond an obstruction or an artificial anus. Pressure on the organs, as by tight-lacing, &c., may lead to the same result.

4. *Degenerations.*—Those morbid processes to which the digestive organs are subject, and

which essentially consist in the conversion of the tissues into materials of a less complex chemical composition than normal, associated with a diminished vital activity, may affect any or all of the structural elements of which the digestive organs are composed. Albuminoid infiltration or cloudy swelling is the invariable accompaniment of inflammation of the epithelial and muscular tissues. Fatty degeneration is a further result of inflammation, with caseation and occasional calcification. Although not the commonest organs to be so affected, yet not infrequently the intestine and stomach are the seat of the so-called amyloid or lardaceous degeneration, and not always limited to the vessels, but affecting the epithelial, fibrous, and muscular coats. The liver is especially liable to undergo degeneration, both fatty and albuminoid. Deposition of pigment may be found in the deeper epithelial strata of the mouth in Addison's disease, and in the liver in certain cases of intermittent fevers.

5 Changes in the secretions of the various glands may result in the production of *calculi*—salivary, pancreatic, or biliary.

6. *New Growths*.—There is scarcely any known form of neoplasm which may not be found in some region or another of the alimentary tract.

The new growths limited to the epithelial coat, or commencing in it, are conchyliomata, papillomata, encephaloid, and scirrhus.

In the fibrous tissue occur sarcoma, fibroma, myeloid, adenoid, gumma, enchondroma, and lipoma.

In addition there may be polypi, or tumours of the mucous membrane, myxomata; muscular tissue tumour; cysts, and vascular growths, such as ateri and hemorrhoids.

7. *Traumatic*.—Certain parts of the alimentary tract are, from their position more liable than others to external injury. Incised and punctured wounds of the mouth, œsophagus, stomach, intestines, and liver are of occasional occurrence, and rupture of the abdominal tissue is sometimes met with. The injection of corrosive substances may produce destruction of certain parts of the canal, and wounds may be determined by foreign bodies, as pins, fish-bones, &c., which have been swallowed.

III. Malformations and Malpositions.

1. *Hereditary*.—Of these the most important are hare-lip; cleft palate; fistulous communication between the pharynx and the exterior, or between the gullet and trachea; intestinal cæcæ; imperforate anus; herniæ.

2. *Acquired*.—Malformation and malposition of the viscera may follow from disease. Communications between the stomach and intestines, or between different coils of intestine, or between the gall-bladder and the gut, may result from chronic ulceration. Many herniæ are not developed until long after birth, from violent strains, &c.

Stricture of various parts of the canal is frequently associated with the healing of ulcers, and with new growths. Dilatation of the canal is apt to occur in the proximal, and contraction on the distal side of such strictures. The intestines may be considerably displaced from adhesions following peritonitis. Twists (volvulus), intussusception, internal strangulations,

and prolapsus ani, are more or less common affections of the intestines.

IV. *Abnormal Contents*.—Concretions, chiefly of phosphate of lime, are found occasionally in the intestine. They usually are made up of consecutive layers of material deposited by the mucous membrane. They frequently have as a nucleus some foreign body. Similar bodies formed of chalk or nunguis which has been swallowed have been met with. Foreign bodies, such as pins, bones, fruit-stones, coins, &c., may also lodge in the alimentary canal.

Parasites.—The chief of these are *Sarcina ventriculi*, in the stomach; *Tænia solium*; *T. mediocanellata*, *Bothrocephalus latus*; all inhabiting the small intestines. *Tænia Echinosococcus* (hydatid) in the liver. *Ascaris lumbricoides*, chiefly met with in the small intestines; and *Oxyuris lumbricoides* (thread-worm) almost confined to the rectum. A few other species are rarely found.

The gases of the intestines may be so largely increased in quantity as to constitute an abnormal condition.

W. H. ALLCHIN.

DILATATION (*dilato*, I enlarge)

Ætiology.—Dilatation of any of the cavities, tubes, or orifices of the body may either result from increased pressure from within, or from diminution in the resisting power of the walls of the tubes or cavities. These two causes are frequently combined, and, indeed, the latter is often the result of a long continuance of the former. Increased pressure from within may be due either to increased secretion of the normal contents of the cavity, or to some other effusion into it. This is the usual cause of dilatation of the closed cavities of the body, we have examples in the ventricles of the brain, the pericardium, the synovial cavities, the bursæ, the follicles of the thyroid body in cystic goitre, and the Graafian vesicles in some forms of ovarian dropsy. In the various tubes of the body, increased pressure from within may arise from obstruction, and the consequent accumulation behind the seat of obstruction of the substances which it is the function of the tubes to transmit.

VARIETIES AND CHARACTERS.—1. *Cystic dilatation*.—In tubes which begin by blind extremities the result of dilatation is generally the formation of a cyst, and this is the usual mode of origin of the large class of *retention-cysts*, or *cystic dilatation*. We have examples in the sebaceous cysts, in the cysts of mucous membranes due to the ducts of the mucous glands becoming obstructed by the products of catarrhal inflammation, in cysts of the kidney formed by dilatations of the Malpighian capsules and uriniferous tubules, and in dilatations of the gall-bladder, and of the pelvis of the kidney.

2. *Uniform or cylindrical dilatation*.—In tubes not beginning by blind extremities, the effect of the obstruction is usually to produce a *uniform* or *cylindrical*, and not a cystic dilatation, though sometimes one part of the wall will yield, and so cause a diverticulum or sacculus. These uniform and cylindrical dilatations may occur in all the tubes of the body. They are met with in the

œsophagus and all parts of the digestive canal, in the heart, veins, bladder, ureters, bile-ducts, &c. This form of dilatation may be attended either with thickening and hypertrophy, or with thinning and atrophy of the walls. Usually, when the tubes are in the main muscular, hypertrophy occurs, from increased exercise of the muscular fibres in their efforts to overcome the obstruction; but when the walls are mainly fibrous or elastic, they generally become atrophied and thinned.

3. *Compensatory or collateral dilatation.*—Another form of dilatation from increased internal pressure may be termed *compensatory* or *collateral* dilatation; it is produced by the tubes having to transmit an increased quantity of fluid in consequence of the obstruction of other channels. Besides the blood-vessels, we may meet with examples of compensatory dilatation in one ureter when the other is blocked, and in the bronchial tubes and other parts. Resembling this form in its mode of origin is the dilatation caused by tubes having to transmit substances of too large a calibre, as, for example, in the passage of calculi down the gall-duct and ureters.

4. *Dilatation from changes in the walls.*—The last class of dilatations consists of those due to diminished power of resistance in the walls of the tubes or cavities. The most important examples of this class occur in the circulatory and respiratory systems; in the heart from fatty degeneration; in the arteries from atheromatous changes. In the respiratory organs it occurs both in the bronchial tubes and in the air-cells. Here, however, the loss of resisting power is itself usually caused by prolonged increased pressure from within; which in the air-cells, as their walls are elastic and not muscular, rapidly causes atrophy, and subsequent dilatation.

W. CATLEY.

DILUENTS (*diluo*, I wash or dilute).

DEFINITION.—Remedies which increase the proportion of fluid in the blood.

ENUMERATION.—Water is the only real diluent. It is given for this purpose in various forms—soups, ptilians, barley water, toast and water, milk, lemonade, aerated waters, &c.—to quench thirst, and increase secretion.

Uses.—Diluents are employed to lessen thirst, as in fever and diabetes. As the thirst may depend upon local dryness of the throat, as well as upon general want of fluid in the system, the power of water to quench thirst may be greatly increased by adding to it a little vegetable or mineral acid, or some aromatic, such as lemon or orange peel, which will stimulate the flow of saliva, and thus tend to keep the mouth moist after the liquid itself has been swallowed. The thirst-quenching power of water is also aided by the addition of mucilaginous substances, such as oatmeal, or linseed as linseed-tea, which, leaving a mucilaginous coat on the inside of the mouth and pharynx, retard evaporation, and thus lessen the dryness of the mucous membrane.

T. LAUDER BRUNTON.

DIPHThERIA (*διφθήρα*, a skin). —SYNON. *Fr. diphthérie, diphthérie*; Ger. *Diphtheritis*.

DEFINITION.—A specific, contagious, æsthenic, general disease, which sometimes prevails as

an epidemic, and is endemic in certain places. It is characterised by the exudation in various situations—particularly on the mucous surface of the soft palate, uvula, tonsils, pharynx, larynx, and trachea—of a peculiar cæcoplastic lymph, which, together with epithelial cells, generally forms a thick, tough, and stratified pellicle or false-membrane—a stroma made up of mucous and epithelial cells, arranged in layers of the cæcoplastic exudation.

NAME AND SYNONYMS.—In 1826, Bretonneau of Tours, in his work, entitled *Recherche, &c. sur la Diphthérie*, created the name, and first pointed out the true pathology of the disease. In his latest memoir (1855) he substituted the term *diphthérie* for *diphthérie*, having discovered that the disease is not of an inflammatory character. *Diphthéria* was a word almost unknown in English medical literature till 1859, when the Sydenham Society published a volume of memoirs on the disease, translated by Dr. Semple from the French of Bretonneau and others. The name, slightly modified, has now been appropriated by all European languages; and at present there is no other word which can correctly be said to be synonymous with it, although it is equally true that the disease diphthéria has been described under many names, without, however, an exact appreciation of its distinctive character, by Hippocrates, Celsus, Sydenham, and others, from the dawn of medical history to the present day. 'Croup,' in cases named and described by Home, Cheyne, West, and others, is identical with Bretonneau's 'croup,' which he also calls tracheal and laryngeal diphthéria; but, nevertheless, croup and tracheal diphthéria being described by the majority of British authors as different diseases are not in a literary sense synonymous terms.

GEOGRAPHICAL DISTRIBUTION.—Epidemics of diphthéria have occurred in many countries far apart from one another, and differing essentially in physical features and climate. In recent years the geographical distribution of the disease seems to have become greatly extended, a circumstance which is probably attributable to the increasing intercommunication of peoples. Diphthéria has its favourite localities—localities in which it is always endemic, and frequently epidemic. Among such places may be particularly mentioned Florence and Paris.

ÆTIOLOGY.—The disease is contagious. Apart from endemic and epidemic causes affecting its maintenance in foci, and its outbursts at particular times and in particular places, there are ætiological influences belonging to individuals in respect to:—

1. Accidental Predisposing Causes;
2. Age; and
3. Heredity.

1. *Accidental Predisposing Causes.*—Poverty and its concomitants—unventilated filthy lodgings, scanty clothing, and imperfect alimentation—impart to individuals a receptivity for the contagium of diphthéria. A similar receptivity exists in tuberculous persons and in all cachectic subjects. Scarlatina, measles, and whooping-cough peculiarly predispose to diphthéria. In twenty years, Barthes observed 605 cases of scarlatina: in 95 of them, that is, once in about

every six cases, diphtheria occurred as a secondary disease. Diphtheria of the air-passages may occur also as a secondary disease after a common inflammatory sore-throat, a circumstance which has led some to hold that diphtheria is an inflammatory disease. Recently-delivered women receive easily the diphtheritic poison. During epidemics the influence of the predisposing causes now enumerated is sometimes strikingly exemplified.

2. *Age*.—Diphtheria is most common between the ages of two and ten. Few persons are attacked after thirty; but there are occasional victims at all ages, from the earliest infancy to old age.

3. *Heredity*.—Diphtheria is not an hereditary disease; but a special aptitude to receive and develop the poison evidently pertains to certain individuals and families. This statement is borne out by the statistical enquiries of Morelli, Nesti, and others in relation to the recent epidemics of Florence; but the facts which establish it beyond a possibility of doubt are the numerous cases of particular families being desolated by diphtheria at intervals of years, and when the members attacked were widely separated. For example, a child died this year of diphtheria in Paris: a sister died of the same disease two years ago in Florence; about the same date, an elder brother similarly perished at the Cape of Good Hope; and the mother of these children was in childhood nearly carried off by the same disease. Family histories of this kind are so numerous, as to lead to the conclusion that there is often a certain stamp of similarity of constitution pervading a family, in virtue of which its members are specially disposed to receive and develop the diphtheritic contagium.

NATURAL COURSE.—Diphtheria has a tendency to run a definite course, as may be well seen in cases which are benignant or of moderate severity. In the cases termed *benignant* by authors—cases more numerous in some epidemics than in others, and commonly met with at the beginning and decline of most epidemics—the disease runs its entire course in from eight to ten days. In this class of cases complete and rapid recovery often takes place, not only without medical treatment, but also in spite of the most objectionable measures having been adopted. In many benignant cases the exudation is limited to the tonsils and pharynx, but sometimes it invades the larynx and trachea; nevertheless, under both circumstances, the false-membrane begins to loosen spontaneously, and to be got rid of between the fifth and seventh day. In cases of very malignant type—both in those which set in suddenly with intense symptoms, and in those which begin insidiously—the disease may run its course from health to death in less than one day, or, according to the greater or less severity of the poisoning, the fatal issue, or the dawn of recovery, may not occur for several days.

Incubation.—There is a great diversity of opinion as to the maximum period of incubation; but the general opinion is that it does not exceed a few days. There are facts and reasonings, however, which suggest the possibility of the diphtheritic poison remaining

dormant in the system for weeks or months, till called into activity by favouring circumstances.

Invasion.—The invasion of the disease is generally occult and insidious. Slight fever, drowsiness, general discomfort, a little languor, loss of appetite, prostration, diarrhoea, rigors, palles, tickling cough, husky voice, and hoarseness, often usher in diphtheria; but as these symptoms, separately or in conjunction, may occur in children from a multiplicity of causes, they assist in forming a diagnosis only when carefully studied in conjunction with one another, and with surrounding circumstances. It is, therefore, very difficult in most cases to fix the exact date of the commencement of the disease. Three or four days may be passed without the manifestation of characteristic signs, the patient during that time presenting no marked indications of seriously deranged health. The invasion-symptoms are sometimes so slight as entirely to escape notice. The disease may suddenly explode without the smallest warning, by an attack of stridulous breathing; on looking into the throat we may then find false-membrane covering the tonsils and pharynx, and extending into the air-passages, so as dangerously to obstruct the passage of air into the lungs, and excite spasmodic exacerbations of dyspnoea. Sometimes, on the first, second, or third day of the disease, the patient is carried off before any exudation has taken place, the patient dying in a state of profound prostration from primary toxæmia. The diphtheritic poison sometimes kills without producing the diphtheritic pellicle.

SYMPTOMS.—The symptoms of diphtheria are *general and local*.

The *general* symptoms of pharyngeal, laryngeal, and tracheal diphtheria are those of the general specific disease of which they are local manifestations. Wherever the false membrane is situated—whether on the tonsils, pharynx, larynx, trachea, bronchial tubes, nares, eyelids, vulva, vagina, uterus, anus, or on a wound, ulcer, or cutaneous abrasion—its nature is the same. The general symptom never absent is *prostration of strength*. The local symptom absent only in a very few exceptional cases is the *formation of false-membrane*. The other symptoms of most importance, but which are more or less frequently absent, are albuminuria, change of temperature, cutaneous eruptions, enlarged glands, and paralytic affections.

1. *Prostration of Strength*.—This is a constant symptom, but its degree is very variable. Some patients succumb to the primary shock of the poison. In rapidly fatal cases, however, there are degrees of rapidity—there is a gradation of cases from those in which death takes place in less than a day without any characteristic sign except prostration, to others in which time is afforded for the formation of false membrane and the development of some or all of the symptoms mentioned above.

2. *Formation of False-Membrane*.—There is always an exudation of false-membrane unless the patient be cut off before there has been time for its formation. The nature of the false-membrane has been already briefly described in the definition of diphtheria. Its existence is

sometimes not discovered during life, as, for example, in those rare cases in which the exudation commences on the lining of the bronchial tubes, and occasions death by asphyxia before it has extended upwards to visible parts. As a general rule—with, however, about two per cent of exceptions—the exudation begins on the tonsils or pharynx, and next, but not always in continuity, on the larynx. From one to five, six, or even seven days may elapse between the first appearance of false-membrane and its exudation on the mucous membrane of the larynx.

3. *Albuminuria*.—Albuminuria is very commonly met with. The third and fourth days of the disease are the most usual for the first appearance of this symptom; but it may occur on any day from the second to the twelfth without the occurrence being considered unusual. It is sometimes permanent for days, and sometimes continues for weeks after convalescence has begun. Its duration is from one to sixty days. It is often intermittent, and still more frequently—without quite ceasing—its intensity varies at different periods of the twenty-four hours. It does not necessarily indicate a morbid state of the kidney, and—unlike the albuminuria of scarlatina—it is not associated with dropsy. It originates in different causes, which sometimes operate separately or in combination. Probably the chief causes are the rapid waste of tissue and the altered state of the blood, which are very early effects of the poison of diphtheria; there consequently arises a sudden necessity for an enormous discharge of effete matter by the kidneys. Another cause, one likewise almost always in existence, is the ingestion of aliment much in excess of assimilative power, the intermittent character of this cause is probably the explanation of the frequently intermittent character of the albuminuria. A pulmonary cause of albuminuria frequently comes into operation, as in pneumonia, and during the death-agony from all diseases. Obstruction of the air-passages by false-membrane induces albuminuria by producing great congestion of the lungs with more or less asphyxia. Finally, a renal cause may occasionally exist in pre-existing disease of the kidneys; or, secondarily, in their simple congestion from the strain of the extra-work, and their functional feebleness through general deficiency of innervation. The proportion of cases in which albuminuria occurs for one or more days is about one in three cases, but the proportion is different in different epidemics. Albuminuria is not a sign of danger, its prognostic significance belongs not to itself, but to its cause or causes.

4. *Changes of Temperature*.—High temperatures prognosticate danger, but moderate or even normal temperatures are often met with in rapidly fatal cases.

5. *Cutaneous Eruptions*.—Eruptions, varying much in appearance, are sometimes seen in the course of diphtheria. They seldom continue more than three days, and are sometimes visible for only a few hours. If the eruptions themselves were the only guides to diagnosis, the malady might be often mistaken for scarlatina. The eruptions of diphtheria which simulate those of scarlatina are sometimes vesicular, sometimes

like urticaria, and sometimes they occur in bright red patches—rubecular, roscolar or erythematous. They are not followed by desquamation as in scarlatina. The appearance or non-appearance of these eruptions does not influence the prognosis. Eczymoses due to blood poisoning may also occur, and are of course of very serious import.

6. *Enlarged Glands*.—Glandular engorgement is often one of the earliest indications of diphtheritic poisoning. It is not a secondary result of the throat-manifestation, but belongs to the general disease itself. In the recent epidemic of Florence, described by Morelli and Nesti, turgescence of the cervical glands is mentioned as a symptom commonly associated with general anasarca, and an eruption of red, pink, and dark red points on the face, neck, chest, and abdomen. This eruption was sometimes visible for only a few hours and never for more than three days.

7. *Paralytic Affections*.—This important subject is only named in this its natural place, its consideration being more conveniently reserved for a separate article. See PARALYSIS, DIPHTHERITIC.

DIAGNOSIS.—When diphtheria is proved fatal too soon to afford sufficient time for the manifestation of its characteristic symptoms, and also, when the invasion-stage is insidious, the diagnostic difficulties are great. Sanmè believes that the affection designated 'throat-herpes' (*herpes gutturalis*) by Cuhler is a form of diphtheria, an opinion which, if erroneous, is not easily controverted. The difficulty of the differential diagnosis fully explains an opinion, repeated by several authors, to the effect that the diphtheritic nature of an affection cannot be declared with certainty till the membranous deposit has been seen to extend from the tonsils and pharynx to the respiratory passages. Some physicians, among whom is Trousseau think that the herpetic nature of the affection is established when an eruption of herpes appears on the lips. Sanmè says 'Diphtheria commences with focal phenomena which are very varied the form and disposition of the false-membrane are insufficient to enable us to predict the nature of the malady, or to form a prognosis regarding it.' He adds and with truth, if the statement be accepted only as a provisional clinical fact.

'This is one of the most important aphorisms in the doctrine of diphtheria.' Pathologically, however, there can be no diagnostic difficulty in these cases if it be true, as an increasing number of physicians believe, that membranous sore-throat is always diphtheritic.

PROGNOSIS.—The younger the subject, the less are the chances of recovery. This arises from two causes, viz, the smaller power in infancy to resist depressing influences; and the narrowness of the larynx in infancy and childhood. The elements of prognosis belong in part to the individual case, and are in part common to all the cases occurring at the same time and place.

First, in respect to the individual element. The prognosis is unfavourable if false-membrane has been deposited, and continues to be formed on the mucous membrane of the air-passages during the first three or four days of the disease: on the other hand, the prognosis is favourable if these days be passed without formation of false-

membrane on the air-passages, but only *provisionally* favourable, for a sudden membranous invasion of the air-passages may occur during that period. If at the seventh day the air-passages be not invaded, if there be adequate cardiac power, and if a fair amount of aliment be regularly assimilated, the prognosis is very favourable.

We must, however, take into account peculiarities of constitution, the presence or absence of disease prior to the attack of diphtheria, and also the exact significance of each symptom in respect to its individual gravity, its grouping with other symptoms, and the period of the malady at which the prognosis is made.

Secondly, in respect to surrounding circumstances. In cold damp weather the mortality is greatest. The medical constitution of the season, and the character of an epidemic greatly influence prognosis. In some epidemics, in which the local manifestation of the disease is limited to the pharynx, recovery takes place in nearly every case. In an epidemic which prevailed in France in 1847, the mortality was 91 per cent. In the first quarter of 1876 the mortality from diphtheria in the hospitals of Paris was 79.75 per cent., whereas in the six preceding years it averaged only 76.54 per cent.

ANATOMICAL CHARACTERS.—The lesions found after death from diphtheria are *primary* and *secondary*. The *primary* are those found in persons dying during the natural course of the disease, the *secondary* are not direct results of diphtheria, but are consequent upon the complications and retardations of abortive convalescence.

1 *Primary lesions.*—In persons who die during the first two or three days of the disease, in whom there are no complications, and in whom there has not been time for the formation of false-membrane, the only morbid appearance found on dissection is sanguineous congestion of the mucous membranes, lymphatic glands, and internal organs. In those who live a few days longer survive the seventh or eighth day of the disease a similar state of congestion is met with, and there are found on mucous surfaces, particularly on those of the pharynx, larynx, and trachea layers of the characteristic pellicle. The only primary morbid appearances of diphtheria, visible to the unaided eye, are congestion of organs, and false-membrane on certain mucous surfaces. To these has of course to be added a dyscrasia of the blood, which probably exists from the very beginning of the attack.

2 *Secondary lesions*, which are numerous, vary according to the nature and duration of each case. It is particularly noteworthy that in the secondary, anemia replaces the hyperemia of the primary morbid conditions.

To the general statements now made in reference to the morbid anatomy of diphtheria, there are numerous exceptions, and as one of the more important of them may be specified pseudo-membranous deposits in the bronchial tubes, and hepatization of the lungs occurring as early as the second or third day.

A brief sketch of some of the secondary lesions of diphtheria is subjoined:—*Lymphatic glands.*—The submaxillary and parotid are the most usually and the most acutely affected, next in

order of frequency come the superficial cervical glands, the deep cervical glands, and the mesenteric glands. Glands sometimes suppurate: when this takes place the pus is generally found in small circumscribed depôts. They are sometimes infiltrated with a brownish sero-sanguinolent fluid, sections of glands so affected resemble sections of the healthy spleen. *The inner ear.*—This is sometimes invaded by false-membrane, extending from the skin of the outer ear, or advancing by the Eustachian tube from the pharynx. *Connective tissue.*—Sanguinolent and sanguineous effusions are sometimes found in the connective tissue, particularly in that subjacent to mucous membranes coated with the diphtheritic pellicle. In it abscesses are also met with, in the contiguity of engorged and suppurating glands. *Muscular tissue.*—In protracted cases of paralysis, the muscles of the arms, legs, chest, and eye-ball are often found to be more or less in a state of fatty or waxy degeneration. The muscular tissue of the heart is likewise sometimes similarly affected.

Lungs.—Besides the primary specific lesions we may find on dissection anatomical evidence of simple bronchitis, pneumonia, and pulmonary apoplexy having occurred as secondary affections. *Trachea.* Cases have been recorded in which the trachea has been found ruptured, the result of a desperate struggle for breath. In tracheotomy-cases, the pressure of a badly adjusted cannula has frequently caused ulceration of the trachea. The contraction of the ulcer sometimes produces stricture of the passage. *Mediastinum.*—Abscesses of the mediastinum occasionally follow tracheotomy.

Kidneys.—A form of superficial parenchymatous nephritis, resembling the characteristic lesion of scarlatinal albuminuria, is said to be a common pathological condition in diphtheria. Perhaps under the term *parenchymatous nephritis* many cases of simple hyperæmia are included. The condition of the kidneys in diphtheria requires, however, further investigation. The granular and other degenerations of the kidney described having been met with, have probably no peculiar or direct relation to the diphtheria. They may either represent disease which existed prior to the diphtheritic attack, or disease resulting from the general damage to the system induced by that attack, just as it might have been produced by an attack of some other debilitating, blood-disintegrating malady. Be that as it may, it is important to note that in patients who die in the first days of an attack of diphtheria after having had intense albuminuria, the only discoverable morbid condition of the kidney is moderate or considerable congestion. Sanné explains the rarity of the occurrence of oedema and cerebral symptoms in connection with diphtheritic albuminuria by the fact that one kidney only is affected and not both, as in scarlatinous nephritis.

Nervous system.—Even when death has been preceded by protracted paralytic affections, the most minute microscopic examination has generally failed to detect any morbid change in the encephalon or spinal cord. On the other hand, in protracted cases of diphtheritic paralysis, various alterations in the nervous periphery are frequently found.

PATHOLOGY.—Diphtheria is a poison-disease acting primarily upon the whole system; the exudation of caseoplastic lymph is a manifestation of the general poisoning, and not, as Trousseau taught, an infection of the patient by the absorption of the poisonous material of the false-membrane. Gangrenous decomposition of the false-membrane sometimes, however, becomes a source of secondary toxæmia. The poisoning is then not diphtheritic, it is simply the result of the absorption of putrid matter.

TREATMENT.—Few diseases more severely tax the ingenuity and therapeutic resources of the physician than diphtheria. He has to devise and carry out innumerable little details—hygienic, dietetic, and medicinal—which do not admit of minute description, and yet upon the minutiae of which success or failure frequently depends. The treatment must be carried out on a rational basis, no special trust being placed in nostrums, or in any of the so-called specifics announced in earlier and later times, and some of which are still recommended by honest enthusiasts of limited experience. It is requisite to pay the utmost attention to the hygienic surroundings of the patient. From the first it is necessary that decided and well-considered measures be carried out to support life, by the administration of alcoholic stimulants and of easily assimilated aliments. Medicines which have a depressing influence on the nervous system, or which tend to produce dyscrasia of the blood, are to be rigidly avoided. Prostration of strength and dissolution of the blood are conditions which exist to a greater or less degree in every case of diphtheria, and for that reason, the abstraction of blood, purging, and the use of alkalies, mercurials, and antimonials are inadmissible.

From first to last sustaining and recuperative treatment—alimentary and medicinal—is the great aim. If life be maintained for a certain number of days, nature, even in very severe cases, makes a decided curative effort. In other words, when the disease has run its natural course, there is a greater or less attempt at spontaneous recovery. The moment has then arrived when the physician can most usefully intervene with his culinary and pharmaceutical resources. It is his therapeutic opportunity. A somewhat varied and well-planned pepsinated aliment and ferruginous medication, which had up to that stage produced little benefit, will then wonderfully assist nature in accomplishing a cure.

The principal details of treatment may be considered under the following heads.—1 Hygiene. 2 Diet. 3 Stimulants. 4 Medicines administered internally. 5 Applications to the throat and air-passages. 6 Tracheotomy.

1. **Hygiene.**—The covering of the patient must be light; and yet such as to prevent loss of animal heat. The placing of one or more eucathermic bags filled with hot water under the bed clothes, close to the patient, is a simple and an admirable method of keeping the body warm, and of enabling the windows to be opened from time to time, without risk, to relieve the distressing air-hunger, when there is obstruction of the air-passages, intensified by the close atmosphere of a badly-ventilated room. The

temperature of the room ought to vary little, a temperature of about 60° F. being maintained. The patient ought to be carefully screened from currents of air, care being taken that free ventilation is not interfered with. A thermometer and a steaming kettle are indispensable in the room of the diphtheritic patient. After tracheotomy, the maintenance of good ventilation, combined with an equal temperature and a warm moist atmosphere, is a paramount necessity, and, in all cases, and in every stage of cases in which there exists diphtheritic *sepsis*-throat, it is important, as a means of moderating the paroxysms of glotto-pharyngeal spasm, that the air inhaled be soft and warm, and that the temperature be equable. Even in the rare cases in which throat-affection is absent, it is the duty of the physician to take the measures best calculated to secure such an atmosphere as has now been described, for the disease may at any moment manifest itself in the air-passages.

2. **Diet.**—Nutriment is urgently demanded, but it is useless—nay, it is mischievous—to push attempts at alimentation beyond very moderate limits so long as the malady is in the ascendant. Assimilation is then very nearly at a standstill, as is shown by the rapid emaciation which goes on, even when large quantities of food are being put within the patient, and likewise also by the albumin which is passed with his urine. The albuminous urine of diphtheria arises from different causes, but, speaking in general terms, it is correct to say that it arises from no renal lesions, and is the expression of rapid waste of tissues and of the non-assimilation of food. Alimentation is the most important, and also the most difficult part of the treatment. Patients—even intelligent adults—often resolutely refuse food, and feel intense loathing, excited by the mere sight or mention of any alimentary substance, and the food taken is generally rejected at once by vomiting, or if retained it is very sparingly assimilated. To press food upon children in spite of their loathing of it is generally injudicious—to press it upon them in spite of their struggles is sometimes even dangerous, as the excitement and resistance takes more strength out of the already prostrate patient than can be compensated for by forcibly administered aliment. We ought to try quietly to get the child to take frequently small quantities of milk or beef-tea; and when we fail, we must give enemata of beef-tea and brandy.

The food given to diphtheritic patients ought to contain pepsine. The quantity administered must of course be proportionate to that of the food. In respect to the dose of pepsine, it is necessary to remember that genuine British *pepsina porci* is four or five times as potent a digestive as Boudault's pepsine, the mixture generally prescribed in France. Pepsinated pills of pounded raw beef, with a few teaspoonfuls of the expressed juice of raw or slightly roasted beef, are exceedingly useful in keeping patients alive while the disease is expending its immediately destructive powers. When the irritability of the stomach does not forbid the trial, strong egg-flip may be given. A strong egg-flip may be made by beating up together one teaspoonful of concentrated Swiss milk, one teaspoonful of

brandy, and two or three teaspoonfuls of water. To these ingredients, two grains of *pepsina porci* may be added. Patients who have moderately severe attacks of the disease, and convalescents, can generally take such semi-liquid aliments as soups and chicken *purée* [*purée à la reine*]. Occasionally, but not generally, patients can take cod-liver oil. Milk ought to enter largely into the diet of diphtheritic convalescents. In them, as in all convalescents, it is an admirable mainstay, but there are some few cases in which it does not agree.

3. *Stimulants*.—Diphtheritic patients emaciate rapidly; and together with as well as before the loss of flesh, extreme prostration occurs. Under such circumstances, the liberal exhibition of alcoholic stimulants is imperatively demanded as the principal, and when food is rejected, as the only means of supporting life during the most critical period of the disease. This great crisis is not generally prolonged for more than a few days, but stimulants may require to be more or less relied on for a long time. Sometimes for hours or days it may be impossible to give anything more than stimulants, of which the best are alcohol in some form, tea, coffee, and the juice of meat. When all kinds of food and stimulants excite nausea and vomiting it is necessary to discontinue for a time nourishing the patient by the mouth. For some hours—for from six to twelve hours—he must be fed entirely by the rectum, so that the stomach may have an interval of complete rest. In such cases it is a good practice to precede renewed attempts at feeding by the mouth, by one or two doses of creasote and oxalate of cerium. Both can be given in very small bulk, which is a great advantage, and no other gastro-sedatives act less as depressants of the general system. The ordinary so-called creasote of commerce is bad carbolic acid, which, in place of allaying, frequently excites nausea and vomiting. If pure creasote cannot be obtained, pure carbolic acid may be substituted for it. The creasote may be given made into pill with breadcrumb, and the oxalate of cerium either in the form of pill, or wrapped in moistened water-paper as a pulpy bolus. The proper quantity of creasote to give at one time is from half a drop to two drops, and of oxalate of cerium from two to four grains. In the twenty-four hours we may administer as a maximum, according to the age of the patient and the circumstances of the case, from six to eight drops of the former, and from twelve to sixteen grains of the latter. Of the crystals, liquefied by heat, one drop is given in a tablespoonful of thin mucilage. This may be repeated several times in the twenty-four hours. When the remedies now mentioned have failed, the nitrate of bismuth in two or three successive doses of ten grains each may succeed. There are cases in which the nausea is so urgent a symptom that it is impossible, by any medicines, to overcome it. We must then trust entirely to the application of warm poultices, sinapisms, or turpentine-stupes to the pit of the stomach. The hypodermic injection of morphia or the administration of an enema containing hydrochlorate of morphia, is another method of allaying nausea and vomiting, in the gastric irritability of fever

and other diseases, but which is only applicable in a limited number of cases of diphtheria, in those cases in which the asphyxia is far advanced and is advancing. The quantity of hydrochlorate to be administered in clyster depends much on the age of the patient. Sixty drops of the *Liquor hydrochloratis morphine* of the British Pharmacopœia may be given by the rectum to an adult, while from five to ten drops is a sufficient dose in clyster for a child under ten years of age. Besides allaying nausea and vomiting, such a clyster soothes, diminishes the severity of spasmodic dyspnoeal paroxysms, and gives the sufferer rest.

4. *Medicines administered internally* are usually employed either to accomplish some particular object, or to exercise a curative influence on the general disease.

There is another special object for which internal medicines are given, namely, the detachment and expulsion of false membranes from the air-passages. For this purpose the administration of emetics has been considered by many as one of the essential parts of the treatment of laryngeal, tracheal, and bronchial diphtheria. Their use is unquestionably indicated in certain cases, yet the range of their utility is very limited. There are two circumstances which obviously limit the advantages obtainable by emetics, first, if administered at an advanced stage of the disease or at any stage when there exists great prostration, the vomitive efforts exerted must act most prejudicially when they do not produce the desired result of expelling the false-membrane from the air-passages—they must draw dangerously upon the waning strength of the patient, and diminish his chances of pulling through with the aid of tracheotomy. There is here a great limitation of the use of emetics, because the cases are exceptional in which the blockade of the air-passages is effectually relieved by vomitive action, and when no such relief is obtained, the violent efforts exerted by emetics only produce unmitigated evil—a large withdrawal of remaining vital power. Again, unless the exudative stage of the disease be ended, the ejection of false-membrane affords only a brief temporary respite, for new layers are speedily deposited to replace those which have been thrown off. These considerations show the narrow limits within which benefit can be obtained from vomitive action, and how much evil may accrue to the patient when that action is violent. Should it be judged expedient to induce vomiting, the emetic selected ought to be one which generally acts quickly and certainly, and which if it fail to act will not produce dangerous irritation of the intestines or great depression of the system. Tartar-emetic must not be employed. Sulphate of copper, an emetic much recommended by Trousseau and others under the circumstances now being considered, is also objectionable, because if it does not promptly cause vomiting, it will be nearly certain to excite enteritis and formidable diarrhoea. Ipecacuan and sulphate of zinc are perhaps the safest emetics to administer to a diphtheritic patient.

The repetition of dose after dose of any emetic is dangerous practice in diphtheria. For example, we may give, without apparent effect,

successive doses to a semi-asphyxiated patient whose functional life is dormant; and seeing that we give him no relief in the way hoped for, we proceed as our last chance of saving him to admit air into the lungs by tracheotomy. Forthwith the vital powers awake, and the accumulated doses speedily act with violence—the patient has been saved by tracheotomy only that he may die of pharmaceutical poisoning.

Dr. Sanné (*Traité de la Diphthérie*, Paris, 1877) suggests that the recently discovered medicine apomorphia might be tried as an emetic in diphtheria. It possesses properties which seem to recommend it very specially in this disease. This drug is administered hypodermically. It acts very rapidly—in from three to five minutes and supercedes or greatly reduces the duration of the period of nausea. It frequently succeeds when other emetics have failed to act. The advantages which it possesses are, therefore, facility of administration, rapidity of action, and less fatigue to the patient. The only objection to its general use is the difficulty of preserving it.*

Another suggestion of Dr Sanné is noteworthy. He proposes that trial be made of jalorandi, given internally, as a means of producing detachment of the false membrane.

The medicines which have a curative influence on the general disease are few in number. Certain medicines—preparations of iron, for example—are, under certain circumstances, particularly useful in diphtheria.

Of the medicines which have had in their day repute as specifics, or as agents of high therapeutic value, but have now nearly ceased to be so esteemed, a few may be briefly mentioned. Bromine and its compounds, sulphuret of potash, copahu and cubeba, chlorate of potash, sulphate of soda, chloride of sodium, carbolic acid, salicylic acid, chloroform, calomel, quinine, perchloride of iron, and many other medicines have all been proclaimed as specifics, or at least as wonderfully potent in the cure of diphtheria. Perchloride of iron has a decidedly beneficial action under certain circumstances, but this action it possesses in common with other preparations of iron. It neither arrests nor modifies the character of the malady in its early and most perilous stages; but its utility is unquestionable as an adjuvant, when, in the natural course of the disease, a spontaneous curative tendency has begun to manifest itself.

5. *Applications to the Throat and Air-passages.*—With a view to detach, dissolve, or destroy false-membrane, a great diversity of topical applications have been employed. Trousseau, and those who wrote under his inspiration, strongly recommended destruction of the false-membrane by various caustics and solvents. In the (1868) edition of his *Clinical Lectures* which was in the press at the time of his decease, Trousseau insists that the topical treatment is pre-eminently the best treatment of diphtheria, adding that it is as much indicated in this disease as in malignant pustule. Fortunately this doctrine is no longer in vogue, and when topical treatment is still employed in France, it is now seldom by caustics or any irritating substances. Sanné, writing in 1877, expresses the general sentiment of French physicians when he says:—'Cauterization is now

generally abandoned. It has serious drawbacks: it is dangerous: it is useless.'† The practice of attempting to destroy the false membrane by caustics and powerful solvents is unquestionably mischievous. It irritates the parts and increases the exudative tendency. The free application of the official glycerine of borax, by means of a camel's-hair brush, is at least harmless, and seems to loosen the membranous patches. Frequently, washing out the mouth with this preparation, diluted with from four to eight parts of water, is agreeable to most patients, and is useful from the local soothing which it produces. A very diluted solution of hydrochloric acid is equally innocuous, and as a mouth-wash is pleasant and cleansing. Lime-water and lactic acid, used separately or mixed, exercise a powerful solvent action on the false-membrane, and were it possible to apply them to it without their coming in contact with, and thereby irritating the contiguous mucous surface, they might be used with advantage, or at least with impunity. A small quantity of lactic acid added to an aqueous solution of pure glycerine or to the glycerole of borax—one part to fifty of glycerine—is a favourite topical application with some practitioners, and is one which may be used without fear of doing any harm. Catheterism of the larynx, and injection of solvents into the trachea are now generally looked upon as objectionable measures. They still have, however, their advocates. Dr Young of Florence states, as the result of large experience, that he has seen much benefit result from throwing into the throat every hour, by means of a small spray-apparatus, a solution of three drachms of lactic acid in eight ounces of lime water.

Notwithstanding much that has been written in a contrary sense, a careful review of the subject leads to the conclusion that very little advantage is derived from internal local applications, that they are often exceedingly mischievous, and ought never to be used without the greatest circumspection. They do not curtail or greatly modify the natural course of the general disease, and the local benefits which they can confer are limited to soothing the parts, and slightly diminishing the obstruction of the air-passages. Moist warmth applied externally to the throat gives much comfort and is in no way injurious. Only soothing, or at least non-irritating substances are admissible as internal applications. It must be remembered that topical applications can hardly ever be employed in young children without exciting resistant struggles, which agitate and exhaust the patient. The risk of incurring this danger often forbids their employment.

6. *Tracheotomy.*—Besides the perils of the general disease—prostrating toxæmia, difficult nutrition, and paralysis of the heart and respiratory muscles—the patient has the special risk of dying asphyxiated from obstruction of the air-passages by false-membrane. This terrible danger is one of very common occurrence. When nature and art have failed to remove or effectually lessen the mechanical impediment to the admission of air to the lungs, the physician has to decide whether there be any reason against his giving the patient

* Sanné: *Traité de la Diphthérie*, Paris, 1877; p. 419.

a chance of life by making an entrance for the air below the membranous obstruction. If this one remaining chance remain in any degree, however small, he is bound to offer it to his patient. Sometimes no such chance remains. What conditions exclude the possibility of saving life by tracheotomy? That is the question. It is not whether the case be a favourable one for operation, for every diphtheritic patient is an exceedingly bad subject for any surgical operation. The simple question is—Does tracheotomy give the smallest chance of life to a patient who without tracheotomy must inevitably die from asphyxia? The answer to this question may, as a rule, be given in the affirmative, if the obstruction be not below the situation in which tracheotomy is performed. If this rule be followed, the operation will often be performed in very desperate circumstances—circumstances in which the probabilities of success are very small compared with those of non-success. When the pseudo-membranous affection extends to the bronchial tubes—when pneumonia exists—when the diphtheria is an immediate sequel of measles, scarlatina, or typhoid fever—when the asthma is extreme—or when the patient is phthisical—the probability of the operation saving him is small, and yet, in most unfavourable examples of the classes now mentioned, success has been obtained.

JOHN ROSE CORNACK

DIPHTHERITIC.—Relating to diphtheria. The term is applied to the membrane formed in diphtheria, and it is also associated with certain symptoms occurring in the course of the disease such as diphtheritic paralysis. See CHOKERS.

DIPLOE, Diseases of. See SKIN, Diseases of.

DIPLOPIA (διπλός, double, and ὄπτομαι, I see).—Double vision. See STRABISMUS.

DIPSOMANIA (δίψα, thirst, and μανία, madness).—*δίψα* *Osmomania*, Fr. *Manie ébrieuse*, or *crapuleuse*, Ger. *Trunkenheit*.

DEFINITION.—An irritability of the nervous system, characterised by a craving generally periodic, for alcoholic and other stimulants.

ÆTIOL.—This peculiar condition may be brought on by a course of intemperate drinking, but it is seldom the result of that cause alone, and it is not infrequent in persons who have never been intemperate previous to the development of the morbid craving. The occurrence of this form of insanity, as of other degenerative nervous diseases, may generally be traced in the family history of the patients. But sunstroke, a blow on the head, or other direct injury to the brain may excite it, and it may be symptomatic of epilepsy, or of structural disease of the brain. It may be developed at any period of adult life, but most frequently declares itself during the pubescent and climacteric periods.

SYMPTOMS.—An instability of character and indications of peculiar nervous irritability may generally be recognised as having preceded the distinct development of the craving. It is also usual to find such persons as are predisposed to the disorder abnormally sensitive to the influence

of stimulants. Sometimes very small quantities of alcohol produce appreciable intoxication. The duration of the periods of craving is variable; but most commonly they last one or two weeks. The remissions continue for periods varying from two to twelve months. During the period of craving the whole moral being is enthralled by the morbid desire, and the regard for truth, decency, or duty is generally altogether lost. Moderate indulgence in a stimulant may bring on the morbid craving, but the desire is frequently developed without any such introduction. Members of the household in which a patient lives can indeed often recognise the indications of a coming attack by a restlessness and depression which precedes any such indulgence. During the intervals the patient seems, except when the brain has been weakened by frequent attacks, to recover completely, and he generally displays great confidence in his ability to resist the tendency in future. Repeated attacks always produce a permanent degradation, both intellectual and moral, and if the patient live long enough he lapses into a state of dementia. It sometimes happens that some cerebral lesion, of which the dipsomania had been symptomatic, manifests itself in paralytic or convulsive symptoms, and the appearance of such phenomena is often accompanied by a modification of the craving.

DIAGNOSIS.—True dipsomania may easily be and often is, confounded with mere habitual drunkenness. In dipsomania, however, there is, as a fundamental condition, a pathological condition of the brain which manifests itself irrespective of external circumstances of temptation. In habitual drunkenness the craving consists mainly in a desire to keep up a condition of stimulation to which the brain has become accustomed. The habit is the result merely of compliance with a vicious custom, and there is no such priority or independence of external influences in the symptoms as is found in the true disease.

TREATMENT.—Prolonged abstinence from stimulants, and adherence to the tonic regimen, are the only measures from which any amelioration can be hoped for. It is seldom possible to restrain the gratification of the craving without seclusion in an asylum or some similar institution, and even when such compulsory restraint has been successfully enforced for a considerable period, the morbid tendency is seldom eradicated. The present state of British law does not, however, permit us to confine either the dipsomaniac or habitual drunkard unless something more morbid than an abuse of stimulants can be alleged. And it is difficult to see how a law could be enacted which would be effectual without being open to serious abuse. Public attention has, however, been lately very earnestly directed to the subject, and it may be hoped that something will be done towards rendering efficient treatment possible.

JOHN SIBBALD.

DISCRETE (*discerno*, I separate).—This adjective is used in reference to certain cutaneous eruptions in which the spots or pustules are separate from each other, for example, discrete small-pox.

DISCUTIENTS (*discutio*, I drive away).

DEFINITION.—Local applications, which are supposed to remove the congestion and effusion of inflamed parts, and the swelling of the skin over them.

ENUMERATION.—The chief discutient measures or agents are:—Friction; Pressure; Mercury and its preparations; Iodine and its preparations, including the Iodides of Potassium, Lead, and Cadmium.

USES.—These remedies are generally applied over enlarged joints, enlarged glands or cystic tumours. The most powerful amongst them are mercury and iodine and their preparations, either alone or in combination. Their action is aided by heat and pressure. The effect of the former is seen in the Indian treatment of gutta, which consists in rubbing iodide of mercury ointment over the tumour, and exposing the patient to the full rays of the sun, or to the warmth of a large fire. The beneficial effects of pressure are observed in the diminution which takes place in enlarged and swollen joints under the application of mercurial ointment or strapping, the friction with the hand in applying the ointment, and the pressure exerted by the strapping greatly increasing the efficacy of the mercurial preparation in removing swelling. See FRICTION.

T. LAUDER BRUNTON

DISEASE (*dis*, from, and *aeue*, cause).—Fr. *Maladie*, Ger. *Krankheit*.

DEFINITION.—Disease may be defined as a deviation from the standard of health in any of the functions or component materials of the body. See PATHOLOGY.

The expression 'a disease' is frequently used with reference to a supposed unit of causation. Thus, it may be applied to some simple phenomenon, for example, neuralgia, when that phenomenon is the sole effect of a cause, or it may include many concurrent or consecutive resultant phenomena, such as those of syphilis or typhoid fever.

GENERAL CONSIDERATIONS.—It is well known that changes of function and of structure are brought about and influenced by a great variety of agencies. These agencies, some of which act from within, others from without, are recognised as the *causes* of disease. Such changes, whether they be functional, affecting more especially the vital properties of the body, or structural, affecting its physical properties, constitute what is familiarly known as *disease*, which is hence called respectively *functional* or *structural*. These changes are merely the evidence of an altered or perverted action, which is then in operation or has already occurred, the nature of which is considered under the head of *pathology*. When these deviations from health can be recognised during life they are described as the *symptoms* or *signs* of disease. For example, when a person, after exposure, it may be to wet or to cold, or both, is found to have an increased temperature, with a quick pulse and perverted secretions, and to complain of thirst, and pain at the joints with effusion in and around them, we say that such person is labouring under disease, and we call it 'rheumatism,' because that name has been assigned to a complexus of deviations from health,

such as those then presented by this individual. When typhoid poison has been introduced into the body, it leads in like manner to a number of functional and structural changes, which, taken together, constitute what we call 'typhoid fever.' Or again, under certain circumstances there appears to be generated in the system, whether as the result of a tendency acquired before birth or by habits of life, an agency which, acting morbidly, produces a series of phenomena which we call 'gout.' These several forms of disease may be classified in groups, arranged in accordance with the causes which give rise to them, their nature, their seat, their duration, &c. Rules are laid down for the modes of distinguishing or diagnosing one disease from another, for prognosticating, as far as may be, their result; and for their prevention and treatment.

Thus it comes that the discussion or description of any particular disease consists of an account of the causes that give rise to it, or its *Ætiology*, the changes of structure or of function which constitute it, that is, its *ANATOMICAL CHARACTER* and *PATHOLOGY*; the phenomena attending these changes, otherwise, the *SYMPTOMS* and *SIGNS* of the disease, the facts that serve to distinguish this particular disease from other diseases, that is, its *DIAGNOSIS*, the means of forecasting its progress and termination, which constitute its *PROGNOSIS*, and finally the measures by which it may be prevented, relieved or removed that is, its *TREATMENT*. Throughout this work the various diseases are as far as may be practicable, discussed upon this uniform plan.

As thus understood - and it is well to remember it - Disease is an abstraction or relation, and not an entity having a special and independent existence. Physiology has in recent days diffused a clear and penetrating light over many of the processes of life in health, which were previously dark and obscure. Pathology, which is physiology applied to the study of unhealthy function and structure, anxiously follows the footsteps of the sister science. We are therefore not hoping and believing too much when we express our conviction that the time is not remote when we shall be able to trace those early and minute changes which constitute disease, and the causes which give them origin, and that we shall thus be enabled to define in a more philosophical and practical form what disease really is. In the meantime we must be content to work upon the phenomena before us, to investigate so far as we can the causes of disease, how to recognise its presence and its nature, how to estimate its progress and its duration, and finally how to prevent its occurrence or to cure it when it has occurred. These varied and important points will be found discussed as above stated under suitable headings in the articles immediately following, and in other parts of this work.

R. QUAIN, M.D.

DISEASE, Causes of.—**DEFINITION.**—Whatever is capable of damaging the structure of any organ or tissue of the body, or interfering with its function, may be a cause of disease. This definition implies that such causes are numerous, and that of many science is yet ignorant. To give a succinct account of them

is therefore difficult, nor is this difficulty diminished by the fact that, in most diseases, we can trace a succession or combination of causes.

GENERAL CLASSIFICATION.—The causes of disease have been divided into (1) *Predisposing* or *Remote*, (2) *Exciting* or *Proximate*, and (3) *Determining*. Illustrations will explain what is meant by these terms.—Two individuals are exposed to the contagion of typhus in equal degree, one, wearied by bodily and mental labour, 'catches' the disease; that is to say, his condition has *predisposed* him to the exciting cause of the malady, the other in vigorous health, escapes the contagion—the *exciting* cause of disease. Predisposition in fact *prepares* persons by rendering them more susceptible to the influence of exciting causes of disease. Many persons are *predisposed* to emphysema because of hereditary taint, in them the air they breathe is day by day an *exciting* cause of this disease, they contract a bronchitis which, by its attendant cough, *determines* the malady. Such illustrations might be extended to a multitude of diseases and justify the division of causes which the older physicians made. Predisposition may be inherited, or it may be acquired and be due to various accidental causes. In most cases there is a combination of predisposing causes, in a man, for example, lowered by fatigue, want of food, and exposure, debauch will readily excite an attack of bronchitis or pneumonia. Practically, it is often difficult to say how much is due to predisposition, but, though many factors unite in the predisposition to disease, it is possible in most cases to estimate the part played by each. See **PREDISPOSITION TO DISEASE**.

Moreover it is not always easy to distinguish predisposing from exciting causes. Predisposition carried to excess becomes an *exciting* cause of disease, and in many cases there is a combination of both. There are certain distinct exciting causes—for example, heat, cold, or injuries of various kinds, but most of these can claim a predisposing power. The contagia of the acute specific diseases and parasites are good examples of direct exciting causes.

In proceeding to discuss the subject of *Ætiology*, no attempt will be made to separate definitely predisposing from exciting causes of disease. The writer will endeavour rather to indicate as far as possible under the head of each factor of causation the direction in which it especially acts.

1 **Age**.—This has a most important influence as a predisposing cause of disease. In Wagner's *Manual of General Pathology* the periods of age are thus subdivided:—

- (1) Nursing age (infancy)—from birth to 7th 10th month
- (2) Childhood—from 1st to 2nd dentition
- (3) Boyhood—from 2nd dentition to puberty.
- (4) Adolescence—from puberty to 20th-25th year.
- (5) Early manhood—from 25th to 45th year.
- (6) Later manhood—from 45th to 60th year.
- (7) Old age—from 60th onwards.

This division is excellent, but in no definition is there more need to look out for exceptions than in that of age. The term *age* is strictly comparative, some individuals are old at forty, others young at sixty. Persons fail with regard

to particular organs while young in years; and, on the other hand, others acquire an increased power in the same as years advance, of which the brain affords an apt illustration. The minor organs of the body betray the like peculiarities and in the early decay of the teeth, the changes in the hair and the skin, we meet with indications of old age, though the individuals are young in years. But, generally, the predispositions of the young and old are striking by their contrast. The young are exempt from fatty degenerations, which are so common amongst those of advanced life, and, in consequence, many diseases amongst them are, *ceteris paribus*, less deadly, and not only does age, by reason of the changes which naturally occur as life goes on, predispose to disease, but all outward conditions become changed. (Children—speaking generally—are apt to suffer from acute catarrhal affections of the mucous tracts, glandular diseases, skin-diseases, tuberculosis of acute type, scrofulosis, and a variety of complaints traceable to improper feeding, bad ventilation, overcrowding, and to hereditary taint. From acute tuberculosis the aged are almost entirely exempt and they do not suffer from hereditary taint nearly so frequently as the young. The very young and the very old are equally subject to bronchial catarrh, and the mortality from this disease at each extreme of life is exceedingly great. But in the young the predisposition to this affection is almost invariably associated with a predisposition to catarrh of the intestinal tract, and to diseases which indicate a general constitutional depression, while in the old bronchial catarrh is predisposed to by a degenerative change in the lungs themselves, or in the air passages. In childhood there is an active stage of growth and development, and when one important organ is affected the others suffer with extreme rapidity, the excretory system is greatly developed, and hence arises a predisposition to spasmodic diseases—for example, to laryngismus stridulus, and to general or partial convulsions during the excitement of dentition. In the old the tendency to spasm decreases, and convulsions become much less marked. Some of the exanthemata, especially measles, scarlatina, and pertussis, are more common amongst children than adults, which is partly explained by the fact that the latter class have passed through the ordeal of those diseases, and are thus proof against them. Rickets also is essentially a disease of infancy and early childhood.

The onset of puberty is a constant source of predisposition to disease, for with it comes a complete transformation in the mental and physical characters, so that the individual, if not very carefully watched, deviates from even the most perfect health into a permanent tendency to disease. The system at this period—especially in the case of females—is frequently unable to bear anything which interrupts or interferes with its activity. The generative organs undergo great changes, and with them the whole moral and physical nature is altered. At this period of life there is a predisposition to both bodily and mental diseases. In fact, pervertedness of any organ or faculty may be started, and, once started, they are apt to

continue; so that there is established, literally speaking, a permanent predisposition to disease, and this predisposition swells very largely the list of affections which are dealt with under the generic term *Hysteria*. Lung-affections—excepting pure bronchitis—are more common at and shortly after the time of puberty than in previous years, but, excepting in the instance of phthisis, hereditary taint is less manifested than during childhood. Even hereditary epilepsy is, if postponed beyond early years, likely to be postponed to the period of adult life.

As has been said, the degenerations of organs and tissues begin to show with much uncertainty, but after the fortieth year of life we almost invariably meet with one or other of them. Their degree and their consequences vary with the surroundings of the individual—with his habits, temperament, occupation, and like influences. Diseases of the large vessels are especially common at this epoch, such as aneurisms of the aorta and of the large arterial trunks in the extremities. Henceforward all the diseases peculiar to advancing age become common. The results of previous disease are now declared by a decided predisposition to exciting causes which have been hitherto without effect. Old age is a relative term. A man is old and predisposed to trifling excitements because his lungs have lost their elasticity, or his brain its regularity of circulation, or his heart its vigour—in each of these cases, as in a host of others, the predisposition is strictly one of degeneration. Again, inherited diseases do not declare themselves in some cases till the later years of life, and of this carcinoma is a striking example. The old are predisposed to lowering diseases—low pneumonia or bronchitis, and to a variety of nervous affections which the vigorous can resist. In them the failing heart-power tells a tale; they are the subjects of general vascular dilatation; and, in short, they succumb to insignificant exciting causes, because of the general or partial decay of the tissues and textures of the body.

2 **Heredity** is a prolific source of predisposition. There is amongst men not only an inheritance of such prominent diseases as phthisis, but of peculiarities in the manner they meet and pass through minor ailments. Thus, in families with a 'nervous history,' we meet with predisposition to headaches of nervous type, irregularities of digestion in the form of diarrhoea and vomiting, and a multitude of conditions which have of late been ascribed to vaso-motor disturbances. The members of some families live long in spite of exposure to almost every exciting source of mischief, and contrast most favourably with others who, as far as one can determine, have all things in their favour. There is no doubt that the effects of syphilis, malformations, gout, the hemorrhagic diathesis, and tuberculosis are handed down from generation to generation. Of many minor complaints there is less certainty; but it is exceedingly probable that persons are predisposed to bronchitis and other catarrhs by inheritance. It is acknowledged that epilepsy descends from parent to child, and that, in fact, individuals, because of heredity, are often the subjects of nervous diseases excited by causes

which those free from taint are enabled to throw off readily. The various forms of insanity are striking examples. It is supposed that the inheritance lies in the tissues themselves—that there is a something in the tissue-elements which predisposes to certain diseases in certain families. It has been asserted that there is even a predisposition by inheritance to the acute specific diseases—such as typhoid fever and diphtheria, and some remarkable occurrences in this country strongly bear out this view.

3. **Intermarriage.**—Intermarriage certainly predisposes to disease, but it is not easy to determine how far its predisposing powers extend. Breeders of first-class animals practise intermarriage, and thereby develop speed, quality, and endurance in the offspring. It is beyond question that this practice of breeders of race-horses is eminently successful for the time, but it by no means follows that the permanent results are good. We are bound to look not only to the immediate, but to the ultimate results of intermarriage—in short, to decide whether intermarriages predispose to disease, to the injury of the community. But no rule, free from exception, can be laid down on this subject, for beyond all doubt many intermarriages have led to both physical, moral, and mental advantages. There is no doubt that malformations are handed down, and that where these are marked in families it is injudicious for persons to intermarry. Where also, for example, serious diseases, such as phthisis, have been met with on both sides, it is most advisable that intermarriage should not take place.

4. **Sex.**—There are great differences in the organs and functions of the sexes, and in consequence a great contrast in their predisposition to disease. The female is more delicately constructed than the male, and those organs which the two sexes possess in common differ in weight and in 'fineness,' and a general consideration at once indicates that the female is less fitted than the male to resist many exciting causes of disease. This is particularly evident at climacteric periods of life, with the onset of puberty girls suffer far more than males, and especially from a variety of reflex spasmodic disorders, which require but little provocation for their development. All the phenomena classed under the head of hysteria often occur at this period. At the same time, and shortly afterwards, there is a tendency to ulcer of the stomach, to persistent constipation, to peculiar attacks of neuralgia—especially of the intercostal nerves, and to acute rheumatism, lapsing into the subacute or chronic kind. Anæmia and chlorosis are also common at the period of puberty, and if then neglected they are apt to persist, and predispose the individual still more to disease.

Even so early as the period of puberty the external circumstances of the sexes differ, and on this depends, in a certain measure, the difference in their predisposition. Education, domestic habits and customs, and, above all, occupation, play an important part. But, underlying these outside influences, there is inherent in the sexes a difference in predisposition; for when they are exposed, as often happens, to the same surroundings, they suffer from widely sepa-

ated diseases. Males are more subject to epilepsy, tetanus, gout, diabetes, locomotor ataxy, venereal diseases, and acute lung-infections, than females. The list shows that occupations which involve hard mental and bodily work and constant exposure explain some of the varieties in predisposition. It is probable that females are more frequently ailing than males, but very often their illnesses are associated with the menstrual functions, and are trifling in degree, and, though more males are born than females, towards the latter years of life the average of the sexes becomes more equally balanced, because the mortality of males is greater than that of females. It is sufficient to allude to the fact that pregnancy and lying-in predispose females to diseases from which males are entirely exempt, and that there is a considerable difference in the sexes as regards venereal affections, both as to predisposition and the effects of that predisposition.

5. **Temperament** is important as predisposing to disease. Persons of *sanguine* temperament are disposed to congestions of organs and hæmorrhages, on comparatively small provocation. *Phlegmatic* individuals are the subjects of those diseases which are readily excited by want of mental and bodily energy and activity. A third set belong to the *nervous* temperament—they are easily excited and easily depressed, so that excitants cause either a form of hysteria or hypochondriasis, for example. The predisposition amongst this class is constantly met with in diseases of an acute character. Nervous persons suffer quickly from delirium and other brain-symptoms, which aggravate and render dangerous an otherwise hopeful malady. In the acute specific diseases this is particularly manifested, nervous people are undoubtedly predisposed to them, and when once attacked are predisposed to dangerous complications. Practically we meet with 'mixed' temperaments, though one perhaps especially prevails. See TEMPERAMENT.

6 **Climate and Locality.**—These differ widely in their predisposition to disease. Persons who have been accustomed to a particular climate frequently suffer when transferred to one differing from it; and on the other hand the sick often benefit by change. Particular diseases flourish in particular climates, and particular organs suffer. In the tropics various endemic fevers prevail which are unknown in this country, for they cease to exist when the temperature sinks below a certain level (about 60° Fahr.) Frost very often cuts short epidemics in our own country in like manner. Particular organs are predisposed to disease by climate—the liver in the East Indies, the lungs and the kidneys in regions where the temperature is capricious. Climates differ as regards air—whether moist or dry, hot or cold; but besides these things the topography must be considered, and the elevation of districts. Plains, mountains, and valleys have various predisposing influences, and while much of such influence depends on the configuration of the country, no little is due to the nature of the soil. No better proof of the latter fact can be given than that yielded by the observations of Dr. Buchanan, who has shown that where a proper system of drainage of soil-water is carried

out, the tendency to pulmonary diseases is very greatly diminished. Clay soils are cold and damp and favour diseases aroused by these combined agencies; sandy and gravelly soils readily drain themselves, are warm and dry, and thus far tend to protect those who live on them against disease. Climates are also modified by trees, rocks, rivers, lakes, &c. Detritus carried down by streams and deposited along their banks or at their estuaries, lux. like ground vegetation and its decay, an undoubted predisposing influence. Particular districts also predispose to certain diseases. Crohnism is most common in close valleys, urinary calculus is endemic in many districts of Great Britain and elsewhere. In some circumscribed areas in Scotland, in Norfolk, and other districts, individuals are especially liable to stone. The influences of climate are well shown by the electric conditions of the atmosphere; some persons are so predisposed that they can foretell a thunderstorm by the change in themselves. Fog in large cities depresses most people, and it is not too much to say that many diseases may be traced to a predisposition which 'bad weather' has started. Alcoholism has been provoked in this way. It is clear, therefore, that under the head of climate there are many combining influences, which affect the moral, mental, and bodily nature of individuals, and through one or all may predispose to disease. In this country, and probably elsewhere, those who dwell on mountains are less liable to disease than the dwellers on plains, marshy plains especially predispose. It should be remembered, however, that it is not climate alone which varies the predisposition amongst persons residing in different regions, for their habits, diet, &c., differ far more than the climate in which they dwell, and predisposition to disease should never be ascribed solely to climatic conditions unless accidental influences have been investigated and eliminated. See CLIMATE.

7 **Town and Country.**—The influences of town and country, as predisposing to disease, require a separate consideration. With them may be considered dwellings, and a variety of minor sources of predisposition. The mortality of country districts is less than that of towns, but towns differ in this respect amongst themselves. The health of the largest city in Great Britain, for example, compares favourably with any of the large manufacturing towns and with many rural communities. It is easy to understand that differences must depend on the occupation, food, and habits of the people, and on their external surroundings—air, light, drainage, and like conditions. In large towns occupations are more lowering than in country districts, while the physical and mental strain is greater, and has fewer interruptions. Late hours, intemperance, and prostitution prevail in towns; but it is by no means certain that, in proportion to the population, these ills are less frequent in the more remote districts. In towns overcrowding checks ventilation, makes

* Imperfect drainage leads to what are popularly known as 'damp walls' in dwellings, and thus predisposes to pulmonary diseases by interfering with ventilation—in fact, by preventing the admission of pure air into such dwellings. This truth bears out the teachings we have derived from Dr. Buchanan's investigations as to soil and air.

drainage difficult, so that subsoils become saturated, clouds the atmosphere with smoke and dust, intermingles the excreta (amongst the lower classes) so that succeeding generations are stunted in their development, and in a variety of other ways predisposes to disease. But in some towns these evils have been obviated by sanitary measures, and as a consequence towns often predispose less than country districts to diseases due to defective drainage and overcrowding. Some startling illustrations of this fact have occurred since sanitary science has been acknowledged to be of national importance. In villages, for instance, reputedly 'model,' epidemics of disease associated with defective drainage and evil domestic arrangements have decimated the inhabitants, and the virulence of these epidemics has been greater than that of those met with in large towns. The latter are now-a-days for the most part better drained than country districts, thus milk-epidemics of typhoid fever have been imported into large cities from isolated farms where the drainage alone seemed to be at fault. Amongst children, rickets, scrofula, and tuberculosis are far more prevalent in town than country. The mortality amongst young children is far greater in towns than country districts. Adulterations are an evil in large communities, affecting people of all ages. From many of these country districts are free, and especially is this true as regards milk. So while dwellers in the country may have bad drainage and bad houses, they have pure air as a rule, every opportunity of breathing it out of doors, and unadulterated milk. Even the alcoholised drinks in many country districts are home-made and harmless when compared with the adulterated raw spirits taken by the lower classes of large towns.

8. *Hygienic Conditions.*—One of the most common causes of disease coming under this head is want of cleanliness. To this is due a variety of skin-diseases, such as eczema of the scalp in children, diseases caused by pediculi, &c. It interferes with the functions of the skin generally, and by it even a common cold is modified. Clothing is a part of this subject. Insufficient clothing is a most important source of predisposition, amongst the rich as well as amongst the poor, for, though the climate of this country is so variable, corresponding adaptations of dress are for the most part neglected. Flannels worn day and night also predispose to disease. Clothing is used to prevent the loss of heat, which occurs in three ways—by radiation, conduction, and evaporation, and a careful adaptation enables us to modify these sources of loss in such a way as to obviate a predisposition to disease. There is probably more care taken in tropical climates to regulate the heat of the surface than in the temperate zone. A very common cause of predisposition to disease is neglect of proper bedding. Deficient ventilation and overcrowding are prolific sources of mischief. Overcrowding without ventilation is one of the greatest evils of our chief cities and towns, and not only is it in their homes and workshops that populations are overcrowded, but in their places of recreation, such as theatres, and in their places of religious worship. Briefly it may be said that overcrowding predisposes to moral, mental

and physical deterioration; to epidemic diseases, and especially to typhus fever; to pulmonary affections; and to a variety of nervous diseases. By lowering the *morale* of populations it increases all other predispositions, and, in fact, passes into an active exciting cause of disease.

9. *Occupation.*—This is a common cause of disease, and is often associated with want of proper hygienic conditions. The overcrowded in work-rooms breathe an impure air, an air loaded with carbonic acid, irritant particles, and various exhalations, and thus are liable to disease. Miners breathe an air laden with carbon; knife-grinders inhale fine particles of metals; marble polishers and masons are in the same plight, in all three cases occupation, combined with neglect of hygienic precautions, leads to pulmonary diseases. Occupation is in many cases a direct exciting cause of disease, for example, workers in arsenic, antimony, copper, lead, the mineral acids, &c., suffer from the poisonous effects of these substances. But oftentimes they escape the direct influences, yet are subject to a predisposition to various diseases, as a consequence of their occupation. Various other occupations, such as those of tailors, shoemakers, milliners, and brain-workers, predispose to disease in different ways.

Too much work and too little work (mental or bodily) predispose distinctly to disease. Continued overwork reduces the system generally, and special organs in particular, according to its nature. A coachman, who uses for many hours his pectoral muscles in driving, suffers chiefly in them when he has an attack of muscular rheumatism. So also those who use the brain too much in intellectual work are predisposed to functional, and even to organic derangements of the nervous centres. Physical overwork is often conjoined with exposure and improper or irregular food-supply and the combination has a marked effect. It has so predisposed armies to disease that their ranks have been decimated by fever, pneumonia, and bronchitis, far more than by the cannon or by the sword. Not a few medical men have been affected by the contagia of the acute specific diseases, because when exposed to them they were worn out by bodily and mental exertion, and by protracted fasting. Overwork reduces the nervous power, and thereby strikes at the very root of the healthy status. On the other hand a sluggish use of the mind and body are favourable to disease and some persons are so constituted that they cease to be safe when their minds have lost the opportunity of active exercise, and the very fact that they substitute an abnormal intellectual employment is proof of this truth. And what is true of the mind is true of the body. A sudden change from active to bodily laziness predisposes largely to disease.

10. *Air*—The question of air has already been alluded to, in considering climate, occupation, town and country, overcrowding, &c., and it is scarcely necessary to dwell much more on its etiological effects. Air influences the predisposition to disease according to its degree of rarefaction, moisture or dryness, warmth or coldness, and the impurities, mechanical or chemical, which

may adulterate it. In the article **CLIMATE** many of these atmospheric conditions are fully dwelt upon, and their tendencies explained. Impurities in the air are exceedingly prevalent; and mechanical substances suspended in it can excite irritable conditions of the air passages which may pass on to inflammation, and even destruction of the lungs. Throat and laryngeal affections are a common consequence of these impurities. All these chiefly occur amongst certain classes whose occupation loads the air with fine particles as already described. There is scarcely a mineral used in the arts which cannot, by inhalation, excite or predispose to disease. The air may also be rendered impure by chemical agencies, and the moment the normal proportion of its elements is disturbed it becomes a source of disease. Excess of carbonic acid is especially an element of mischief—causing headache, dyspepsia, and nervous depression. The presence of ammonia and of sulphuretted hydrogen is attended by like results. The human economy is, however, so framed that its organs can often very rapidly throw off the evil effects of these gases when breathed in overcrowded rooms, &c., so that no permanent mischief is established. Poisoned air plays a part in the production of scrofula, anæmia, and lowered conditions generally; but it is an incomplete comprehension of the causes of these conditions to set down all to this one. The air, also, may be poisoned by other gases, such as carburetted hydrogen.

The atmosphere is modified by currents—sometimes to the relief, sometimes to the danger of mankind. Winds can remove sources of contagion—they can 'clear the air.' But they can also bring contagion into localities according to many authorities. Cholera and other diseases have, it is said, followed aerial currents—that is, have been carried by them. East winds are a prolific cause of disease, they excite it directly, and carry off healthy individuals, even though the cold be not extreme. Sometimes westerly winds have a dangerous influence, and in the winter of 1877-1878 a wave of disease having many of the characteristics of 'influenza' was carried across England by a west wind.

11 Previous Disease.—Previous disease often predisposes to the same or to some other affection, and no clinical history is of value unless it includes an account of former illnesses. In difficult and doubtful cases a true statement of these often gives the clue to diagnosis, and even patients themselves are alive to the value set upon an accurate account of their life-ailments. An attack of croupous pneumonia predisposes to recurrence, especially during the twelve months succeeding the attack, and it may leave behind a predisposition extending far beyond the original disease. Chorea, acute rheumatism, tonsillitis, and epilepsy tend to recur, as also do the ordinary convulsions of children; but in all these and many other cases it is difficult to estimate the exact part played by derived predisposition, because in all the primary predisposition may be the main agent in the subsequent attacks. In practical medicine it is distinctly recognised that certain diseases predispose to disease, and in

their case recurrence is, very properly, jealously guarded against. Pertussis is supposed to predispose to measles, and *vice versa*. There is distinctly a connection between chorea, rheumatism, and scarlet fever, and these diseases may follow one another in any order. Again, previous disease may leave behind pathological lesions which remain in abeyance until excited by causes which the healthy individual could readily withstand. Pertussis often ends to all appearances favourably, but afterwards the patients may suffer from severe lung-affections, upon trifling exposure to exciting influences. Calcareous deposits in the lungs may excite a new catarrhal phthisis, hepatic mischief followed by collection of gall-stones in the gall-bladder may cause peritonitis and other diseases. Slight complaints are even more marked in their predisposing powers than serious diseases. On the other hand, previous disease sometimes protects individuals and communities, for example, vaccination can save nations from the most terrible of scourges. In the case of scarlet fever, typhus, pertussis, measles, &c., an almost perfect immunity is acquired by those who have already suffered from them. Of course, as with small-pox, no one denies that second attacks of these diseases do occur, but such attacks are wholly exceptional.

12 Mental and Moral Conditions.—Bad news may cause sudden death, or, short of this, may interfere with the functions of particular organs. Sudden mental worry may excite dangerous interference with digestion, or start an abnormal cardiac rhythm. Fear has turned the hair white within a few days or hours in healthy persons. Mental and moral shock can check or increase the flow of urine, and, in fact, can affect all the excreting and secreting organs of the economy. Mental overwork can excite, *per se*, brain-conditions of a dangerous nature, such as hyperæmia or anæmia, and even, it is said, meningitis of simple or tubercular form, according to the inherited predisposition. Unlucky or sudden emotional disturbances can excite serious mischief, just as they can predispose to it. Again, the mind is affected by imitative influences, thus chorea is excited in some individuals by watching choreic movements, and a single hysterical patient may arouse in others symptoms almost identical with her own. The subject of the direct influence of the mental and moral state on disease is, however, too wide to be here dwelt upon.

13. External Physical Conditions.—These are very numerous as exciting causes of disease. Violent over-exertion can cause hernia, hemorrhages, as from the vessels of the lungs, cerebral congestions, and even ruptures of the valves of the heart, and in one or all of these cases lead directly to death. Over-exertion with the voice may be followed by pharyngitis or laryngitis. Syncope has occurred in the most healthy from violent exertion in hill-climbing, in boat-racing, walking and running matches, &c., acute dilatation of the ventricles probably occurring. Various forms of direct injury are frequent causes of disease.

14. Poisons.—Poisonous gases are powerful excitants of disease, and so are poisons generally, whether animal, vegetable, or mineral. They

may kill quickly or excite a disease of long-continued or even permanent nature.

14. Temperature.—Heat and cold carried to excess may prove fatal at once. The influence of severe cold are described under the heading cold, and it is only with the diseases excited by heat and cold in the everyday acceptation of these terms that we shall deal here. Long-continued heat lowers the vital powers, and may excite such diseases as slight eczema of a simple character, or such grave affections as inflammation of the membranes of the brain. Heat may kill suddenly, as in sun-stroke, or excite cerebral mischief just short of death; while in persons of tubercular diathesis it may induce tubercular meningitis; and even more general effects follow severe local applications of heat. Moderate heat applied to the back often depresses the heart even to syncope. Choleraic attacks in this country usually are associated with exposure to immoderate heat.

Cold is the most common cause of disease in temperate climates, especially in the changeable climate of this country. It can excite disease directly, and can affect probably all the organs of the body, causing either disturbed function or organic mischief. Cold, when severe, contracts the vessels, interferes with the circulation, and all vital activity, and in this way may cause death. But it is with moderate degrees of cold we have chiefly to deal. A momentary exposure to a cold draught is as frequent an excitant of disease as general exposure for a long time. A cold draught playing on the cheek may cause facial paralysis, sore throat, or bronchitis, that is to say, cold applied locally may excite disease in the neighbourhood of its application or in distant organs. It is probable, therefore, that cold may act in several ways: (1) it may interfere with circulation; (2) it may affect the extremities of nerves and excite disease by reflex action; or (3) it may check secretions of the skin, the mucous membranes, &c.

We cannot wonder, therefore, that diseases of the throat, larynx, and lungs are frequently excited by cold. Bronchitis and pneumonia are its most common results; and as the young and the old are less enduring of cold than adults, it carries them off with great frequency. Diarrhoea, renal diseases, congestion of the liver, acute and chronic rheumatism, simple dyspepsia, and a host of other affections, are traceable in many instances to cold. Predisposition has much to do with the effects of cold: some individuals suffer from one form of disease when exposed to it, others from entirely different affections. In some, 'a common cold' is most evidenced by severe muscular pains and fever, in others by a nasal discharge, in others by headache, and so on. Some persons never suffer from 'cold' without having an attack of herpes labialis; and numerous similar idiosyncrasies might be given. The effects of cold should always be considered with almost all predisposing causes of disease. 'Cold' is a vague term and not thoroughly understood; there is all the more reason why, when it comes under consideration in individual cases, its precise effects should be most carefully considered and recorded.

16. Diet.—Food and drink can by their abuse excite disease, and gluttony is as powerful an excitant as drunkenness, though in temperance countries this fact is almost completely lost sight of. Excess of food does not refer simply to the quantity taken, but to its quality—its nature, richness, and the times when it is taken. Agricultural labourers eat more than the gentry, but live longer, and the gentry of old-fashioned type are longer-lived than those who frequent the fashionable world. Excess of food overloads the stomach, makes calls upon it which it cannot meet, and dyspepsia is the result. Excess of food, if digested, charges the blood with materials not demanded by the economy, and disease of excretory organs or fatty degenerations may thus be excited. Want of food also excites disease, such as pneumonia, bronchitis, or other catarrh, especially in children, many deaths amongst whom are the direct consequence of improper feeding. When the proper admixture of the elements of food is neglected, disease results, as, *e.g.* scurvy. Particular foods will immediately excite violent gastric catarrhs in some individuals, while others can bear them perfectly well. Putrid food is an active poison. Certain kinds of fish are poisonous in themselves, and some vegetable foods laden with salts of lime are supposed to cause urinary calculi. Water and milk are prolific sources of mischief, through the impurities they so often contain. The drinking waters of large towns are usually derived from rivers, and filtration is not a sufficient purification, so that disease may be excited by their use. Alcohol is a most extensive source of disease: it causes, when taken in excess, cerebral, gastric, intestinal, hepatic, and renal affections, and can lower the system so far as to predispose to other diseases. See **ALCOHOLISM**; and **POISONOUS FOOD**.

17. Epidemic Diseases, Contagion, Malaria, Parasites, and Growths are treated of under separate headings. It is now generally established that the diseases known as the acute specific diseases are mostly direct consequences of some contagium. So among the most common exciting causes of disease we must class the contagia of the several fevers, of syphilis, &c. See **PERSONAL HEALTH**; and **PUBLIC HEALTH**.

J. PEARSON IRVINE.

DISEASE Classification of.—Various classifications of diseases, or systems of nosology, have been adopted by different writers, but it is beyond the province of this work to discuss these arrangements, neither of which fulfils all that is required, or can be regarded as satisfactory. All that can be done here is to point out the characters upon which the chief divisions of diseases are founded.

The first classification deserving of mention is that into (1) General and (2) Local. General diseases include those in which the whole system is involved from the commencement, and it comprehends as sub-divisions (a) The acute specific fevers, and certain other diseases due to the introduction of some malarial agent into the body from without, or in some instances developed within the system, for example, typhus and typhoid fevers, scarlatina, small-pox, malarial fevers, hydrophobia, syphilis

pyrexia and septicæmia. (b) The so-called *constitutional, cachectic, diathetic, or blood-diseases*, some of which seem to depend upon the production of deleterious elements within the system, which are capable of recognition, such as rheumatism and gout; while others are independent of any such obvious pathological causes, but are supposed to be severally associated with a peculiar dyscrasia or diathesis, for instance, cancer, tuberculosis, scurvy, rickets. Local diseases are those which primarily affect particular organs or tissues, each being liable to its own peculiar lesions. Thus we have diseases of the lungs, heart, stomach, liver, kidneys, brain, and the other organs, of the mucous membranes, serous or fibro-serous membranes, skin, periosteum, bone, and other structures. This division into general and local diseases is useful within proper limits, but it must be remembered that general maladies are often revealed or accompanied by local lesions, and that complaints which are originally local often more or less speedily set up general disturbance. Moreover, it is still a question whether some maladies are to be regarded as general or local in the first instance. *See SYMMETRY IN DISEASE.*

Another division of diseases, which applies more particularly to those which are of a local nature, is into (1) *Organic or Structural*, and (2) *Functional*. These terms are self-explanatory, the former implying that there is some organic change in the affected part, which we can discover and demonstrate, the latter indicating that there is mere functional disorder, which is independent of any recognisable lesion. That there are structural changes in many affections which are regarded as functional is, however, highly probable, though our means of observation are not sufficiently powerful to enable us to detect them. In connection with each organ, a special classification of its individual complaints under one or other of these primary headings is usually adopted, this sub-division depending upon the affections to which the particular organ is liable. As illustrations of functional disorders may be mentioned disturbed action of certain organs, as of the heart, causing palpitation, derangement of the secretory or excretory functions, as in the case of the stomach, liver, or kidneys, and many nervous disorders. Organic diseases are exemplified by inflammation and its consequences, alterations in growth and development, degenerations, malformations; and new growths. In this work it has not been deemed advisable to describe the diseases of the several organs according to any definite scientific arrangement, but in some cases an alphabetical order has been adopted, while in others individual writers have been allowed to classify the affections of a particular organ according to their own judgment.

Again, diseases may be classified according to their causation and mode of origin. Thus they are divided into (1) *Hereditary*, or those which are transmitted either directly from parents to children, or indirectly, as the result of a family taint, and (2) *Acquired*, or those which are developed anew in persons free from hereditary taint. When a morbid condition exists at birth, it is said to be *Congenital*. Other divisions,

founded on an ætiological basis, are into (1) *Contagious or Infectious*, and (2) *Non-contagious*; and into (1) *Specific*, or those diseases which are due to a specific cause, and (2) *Non-specific*.

There are other classifications of diseases, which need only be mentioned here. Thus, according to their intensity and duration, they are said to be (1) *Acute*; (2) *Sub-acute*; or (3) *Chronic*. Another arrangement, founded on their mode of progress, is into (1) *Continuous*; (2) *Periodical*, or affections which come on at more or less definite intervals; (3) *Paroxysmal*, or those which are characterised by sudden or acute paroxysms, and (4) *Recurrent*, or diseases which tend to recur. Lastly, according to their mode of distribution amongst communities or in districts, complaints are said to be (1) *Sporadic*; (2) *Epidemic*; (3) *Endemic*; and (4) *Pandemic*. The meanings of these terms are defined under their several headings, but they are sufficiently familiar as indicating the mode of distribution of the diseases to which they respectively belong.

With regard to the classification of diseases which is likely to be permanently adopted in the future for general use, it is probable that this will be founded on a pathological basis, and that, as our knowledge of morbid conditions and processes becomes more extensive, accurate, and definite, it may become possible to establish a system of nomenclature which will be both scientific and practically useful.

FREDERICK T. ROBERTS.

DISEASE, Diagnosis of (*ῥῆσις, intentia*, and *γινώσκω* I know).—*SYNON.*: Fr. *Diagnostic*, Ger. *der Diagnostik*.

DEFINITION.—Diagnosis is the art of recognising the presence of disease, and of distinguishing different diseases from each other. The term is also applied to the result obtained.

GENERAL CONSIDERATIONS.—The *general principles* only of diagnosis will be here discussed. *Special diagnoses* will be treated of in connection with the several diseases to which they have reference.

In many respects diagnosis is a subject of great interest and importance. First, in a scientific point of view, it is essential that all knowledge should be accurate. Secondly, accuracy of diagnosis, founded upon a sound pathology, enables us to frame a scientific classification of disease in its diverse forms. It is also by accurate determination of the nature of the disease which may be present in any given case that we are able to anticipate its course, and to employ the right kind of remedies in its treatment. It is imperfection of diagnosis which leads in many instances to an under-estimate of the value of therapeutical agents; for when the nature of a disease is mistaken we are led to employ improper and unsuitable remedies, the failure of which is then erroneously attributed to the inefficiency of the agents, and not to the unsuitableness of the treatment employed. If our diagnosis had been correct or complete, the remedy selected would more often have had the desired effect.

In order to arrive at a diagnosis we must study the phenomena or characters of each in-

dividual case, and trace its connexion with those groups of symptoms which have been previously recognised and described as belonging to special or distinct diseases. Assuming that the classification has been already made, we proceed to deal with the means which enable us to identify each individual case, and to connect it with a previously classified disease.

MEANS OF DIAGNOSIS.—To obtain accuracy in diagnosis we must be prepared with a knowledge of the several forms and varieties of disease; we must be familiar also with the functions and structure of the several organs of the body in health. It is by observing and comparing the changes caused by disease in the these functions and structures, that we are enabled to discover the presence of, and to determine the nature of disease. In forming, then, a diagnosis in any particular case, the physician must, as far as possible, keep in view the real or the ideal condition of the patient in a state of health. He must endeavour to place him in as natural a position as may be, and as little disturbed by the presence of his attendant, or by external circumstances, as possible. The physician must then obtain a history from the patient himself or from others of the incidence of the disease; and having done this he must proceed to investigate for himself the condition of the patient.

1. *Previous history of the patient*.—The history implies of course a statement of the age and sex of the patient, as well as of his home and his employment—each of which may have a special relation to disease. It should also include an inquiry into the antecedent generations of the patient, and how far he may have any proclivity to congenital disease or malformation. This inquiry should have reference to both positive and negative facts. It should extend not only to the previous existence of disease in the family, but also to the absence of particular diseases or types of constitution. The patient's history should include a statement as regards the diseases and injuries from which he may previously have suffered; the remedies used for them, and the climatic and other influences to which he has been exposed. Nor must the physician neglect to ascertain the history of any children that the patient may have had, as the nature of disease from which the offspring have suffered in many instances throws light upon the health of the parent.

2. *History of present illness*.—The history of the present illness should include the determination of the date of its commencement, its probable cause; and its progress as influenced by external circumstances, including treatment.

3. *The present condition of the patient*.—Here we have to deal with two classes of phenomena, namely (a) those feelings or facts of self-consciousness which the patient describes to us—*subjective phenomena*; and (b) those signs which we ourselves observe—*objective phenomena*.

a. *Subjective phenomena*.—The patient describes to us his feelings—as of strength or weakness, of numbness, tingling or pain, of wakefulness or wandering; he can tell of affections of vision, of hearing, of smell, or of taste; of breathlessness, cough, palpitation, or of feelings of sinking or faintness; of difficulty of swallowing, thirst, loss

of appetite, nausea or sickness, or various sensations and actions connected with the abdomen; of feelings associated with the genito-urinary organs, such as pain or difficulty in passing water; of cramps, spasms, or other alterations of sensation or motility; or of disturbances of sensibility and activity, &c. Each of these signs of deviation from health will have its own value and significance. The physician must at the same time carefully note how far the condition of the patient is in accordance with his statements, and whether there may not be present some reason or cause for concealment or exaggeration.

b. *Objective phenomena*. In studying the objective phenomena connected with disease the physician makes use of his special senses, assisted by the several instruments with which modern science has provided him.

First, in matters of *eye-sight*, he sees the general aspect and expression of the patient, which will include the colour of the skin (such as may result from the fulness or emptiness of the blood-vessels, from the yellowness caused by jaundice from the blueness of cyanosis, or from pigmentation, &c.); the presence and character of cutaneous eruptions (especially in the exanthemata), the expression proper, such as that of ease or suffering, and of depression or excitement, the conditions of obesity and plethora, or of wasting and bloodlessness. He will also observe the position of the patient—how he lies, or sits, or stands, and how he breathes—the appearance of the eyes, the tongue, &c. Further, the sense of sight will be employed in determining conditions of a local or less general nature. Observation must be made of the size, the shape and movements of parts, and of their expansion or contraction. With the aid of special instruments, such as the ophthalmoscope, the laryngoscope, the various specula, sounds, &c. the physician will be able to examine parts of the body of the patient, beyond the reach of the unassisted eye. The chest-measurer or the stethometre will render more exact the information already obtained by the eye and hand as to the size and mobility of parts. The use of each of the several instruments above mentioned, as a means of diagnosis, will be found described under the heads of their respective names, or in the article on **PHYSICAL EXAMINATION**.

The sense of *hearing* tells of the character of the breathing, the voice, and speech of the patient, including cough, hoarseness or aphonia, 'aphasia,' &c. But the ear is especially applied to the study by auscultation of the sounds produced in connexion with the heart, the lungs, and other organs. The signs thus elicited will be found fully described elsewhere.

The sense of *touch* or feeling will communicate a knowledge of the temperature, of moisture or dryness, of size, shape, elevation or depression, of smoothness or roughness, of the pulse or pulsation, vibration, fremitus, of extent of movement, resistance, softness or hardness, and of fluctuation. The accuracy of the results of these observations by touch may be tested by the use of the thermometer, the calipers, and the tape-measure.

The sense of *smell* aids diagnosis in certain cases. The general odour of the patient may

be observed in small-pox, in rheumatism, and some wasting diseases (such as phthisis), and in syphilis; and the odour of particular parts and excretions, as the urine in diabetes, and in cases of the use of certain drugs, or in poisoning. Information is also afforded by the odour of certain discharges, as in oozena, leucorrhœa, cancer, &c.

The sense of taste is seldom employed in clinical investigation, but the physician may make use of the patient's taste, as in tasting the urine in diabetes.

Further aids in Diagnosis.—Having thus summarily described the employment of the special senses in diagnosis and given examples of their use, we may briefly mention some other agencies of more general application. The acuteness of the patient's sense of touch may be determined by the œsthesiometer, the capacity of the lungs may be measured by the spirometer, and the strength of muscles by the dynamometer, the contractility of muscles by galvanism, the force and character of the pulse are determined by the sphygmograph, constant use is found for the microscope, the test-tube, the spectroscope and polariscope, which aid in determining the character of the various secretions or morbid matters that require to be submitted to investigation. The result of treatment may also be mentioned as an aid to diagnosis, as for example, when an indurated sore yields to the use of mercury. Again the knowledge that a person has been in a malarious district enables us to decide on the intermittent nature of certain symptoms that may be present. In some cases it may be necessary to render a patient insensible by anaesthetics, with a view to making a complete examination, or in investigating feigned diseases. The administration of small doses of charcoal has been suggested as a means of determining the presence of a passage through the bowels when there is more or less obstruction exists.

Such then are the means used for taking note of those deviations from health which occur in the several functions and structures of the body, and which constitute what are known as the *Symptoms and Signs of Disease*, these are terms which will be found more specially treated of under the heads *Disease, Symptoms and Signs of*, and *Physical Examination*.

THE DIFFICULTIES OF DIAGNOSIS—It needs scarcely be said here that the practice of diagnosis is not free from great difficulties. We know how hard it is to obtain in ordinary daily life a reliable account or description of any past or present event. There must be still greater difficulty in obtaining an accurate medical history of a patient's case. He has to tell of facts of which practically he may know much, but scientifically very little. He may be forgetful or ignorant on points about which we must need to be informed. He may be inclined to exaggerate or to suppress facts of material import. Nor are the difficulties less in regard to the *objective phenomena* with which we have to deal. The symptoms of a disease are rarely so clear and definite as to mark its nature, that is, to be *pathognomonic*. They are more often slight, undefined, obscure, and to be found with difficulty. The symptoms of one disease may very closely resemble those of another, whilst those

of the same disease will vary at different stages, and in different individuals. Again, the symptoms of a disease may be complicated by the co-existence of those of another disease; whilst a symptom sufficiently striking in itself may be common to, and present in several different diseases. We need only mention, for example, feverishness, pain, cough, breathlessness, and blood-spitting.

These are some of the difficulties which he who has to study the operation of disease in life, has to contend with. He must come prepared for the duty with a knowledge, as we have already said, of the body, its structure and functions in health, and with a knowledge too of those combinations of morbid actions which constitute special forms of disease. For as regards this latter knowledge, all the observations made would remain as isolated phenomena if they could not in each case be grouped as constituting distinct diseases.

We have thus indicated the difficulties of obtaining accurate knowledge as regards both the subjective and objective phenomena. The difficulties are not less when the exercise of the intellectual and reasoning faculties is called upon to analyse, to compare, and to group these phenomena.

The physician may commence his inquiry by tracing up the history of the case and its several elements, a method which is called the *synthetical*; or he may commence by ascertaining the present condition of the patient, and going as it were backwards in his inquiry—a method which is known as the *analytical*. As a general rule, both methods are combined in the practice of diagnosis.

Observers can sometimes arrive at a *direct diagnosis*, aided by the presence of some characteristic symptom or sign of disease. When diseases which are essentially different have symptoms more or less common to both, the physician will have to institute a *comparison* between them, until he finds sufficient evidence, in the presence or in the absence of some distinctive symptom or sign, to satisfy him as to the nature of the disease which is present. By being able thus to trace the absence or the presence of a given symptom, he may be able to exclude the possibility of the existence of one or other of the diseases under investigation. These modes of investigation will be found fully illustrated in the diagnosis of the several diseases described throughout the work.

In conclusion, it must be remembered that these investigations, which call for the exercise of the highest mental faculties, should be conducted without prejudice and without haste. We should never be ready to accept as clear that which is obscure, as established that which is open to question: above all we should remember that, though to err is human, it is our duty to endeavour to ascertain in each and every case, before commencing its treatment, what its real nature is, as far as it may be possible for us to do so. It cannot be too often repeated that the application of a right remedy depends on an accurate diagnosis, and that the prevention and the cure of disease are the aims and ultimate objects of our science. R. QUAIN, M.D.

DISEASE, Duration of.—The duration of a disease signifies the period which elapses between its onset and its termination, in whatever way this may take place. In some instances disease can hardly be said to have any duration, a sudden lesion occurring, which instantaneously, or in a very short time, destroys life; under such circumstances, however, some previous disease has usually existed, though perhaps without giving any clinical evidence of its presence, which determines the occurrence of the sudden result. This may be illustrated by some cases of apoplexy, and of rupture of the heart or of an aneurism. Most affections, as regards their duration, come under one of the three categories already referred to under the classification of diseases, namely, *acute*, *sub-acute*, or *chronic*, but it does not serve any useful purpose to fix any definite limit of time as specially expressed by each of these terms. See *ACUTE*, and *CHRONIC*.

Acute diseases are of limited duration, and in many of them this is remarkably uniform, as may be illustrated by the acute specific fevers and acute idiopathic pneumonia. Even in such affections, however, there are deviations from the ordinary course, instances occurring in which the duration is longer or shorter than that usually observed, and this fact depends on various circumstances, of which the most obvious are the intensity of the disease in any particular case, the previous condition and surrounding circumstances of the patient, the occurrence of complications, and the treatment adopted. Complaints which are *sub-acute* as regards their duration may be exemplified by many cases of whooping-cough and chorea, and by some cases of pleurisy, phthisis, pneumonia, gastric or enteric catarrh, and certain skin-affections. A large number of diseases are *chronic* in their duration, and many of these when once established become permanent, whilst others are ultimately capable of being cured. As illustrations may be mentioned organic diseases of the heart, most cases of phthisis, cirrhosis of the liver, chronic Bright's disease, dyspepsia, many skin-affections, and also morbid growths in various structures.

Some complaints, as regards their duration, can only belong to one or other of the groups just indicated, but a considerable proportion may in different cases be either acute, sub-acute, or chronic. Again it must be borne in mind that a disease may be acute or even sudden in its origin, but afterwards may subside into a chronic malady. Certain affections are chronic as regards their entire duration, but are characterised by the occurrence at regular or irregular intervals of acute or even sudden attacks, lasting a more or less definite time, which course of events is exemplified by cases of ague, epilepsy, and asthma.

FREDERICK L. ROBERTS.

DISEASE, Germs of.—See *GERMS OF DISEASE*.

DISEASE, Prognosis of (*see*, before, and *under*, I know).—*SYNON.*: Fr. *Pronostic*, Ger. *Prognose*.

DEFINITION.—Prognosis is the art of forecasting the progress and termination of any given

case of disease. The term is also applied to the foreknowledge thus obtained.

GENERAL CONSIDERATIONS.—It is a matter of interest and often of great importance to be able to indicate with precision how a case of disease or injury will be likely to advance and terminate. This question must be always present to the physician's mind; and it can rarely be absent from that of the patient and of those who are interested in his well-being. It can easily be seen how much depends upon the answer of the physician to the questions constantly proposed to him, How long is this illness likely to last? How is it likely to terminate? If in recovery, will the recovery be complete or partial? If in death, when and how?

GROUNDS OF PROGNOSIS.—The knowledge which can give trustworthy answers to such questions as the preceding must be founded upon an accurate diagnosis of the nature of the disease from which the individual is suffering, upon the capability of remedies to control it, and lastly, upon an estimate of the constitutional and vital powers of the patient.

First, as regards the *nature of the disease*. Some diseases which are mild in their nature run a definite course and end favourably, take, for example, a simple catarrh. Others commence with great intensity, and come to a favourable or unfavourable termination very rapidly, for instance, Asiatic cholera, of which many of the subjects die in less than twenty-four hours from the time of their first becoming manifestly ill. A third group, such as typhus, typhoid fever, and certain of the exanthemata, run a longer and more defined course, seldom terminating in death except after the lapse of many days, nor in recovery except after a period of some weeks. Another class of maladies, chronic in character rarely acute, such as we see in tubercular diseases of the lungs, render the patient more or less an invalid so long as he lives, and generally end fatally. The like observation will apply to the so-called malignant diseases.

Secondly, the *intensity of the particular attack* affords further grounds for prognosticating the result. Thus in a fever, great prostration, high temperature, and rapid pulse, indicative of the severity of the disease, must lead to the formation of an unfavourable prognosis, just as great debility and wasting, with disturbance of the nutritive functions generally, would indicate a like result in chronic diseases.

Thirdly, in regard of local diseases or complications, whatever the nature of the disease may be, the *organ affected* must form an important element in prognosis. Thus disease of the brain, or of the heart, or of the lungs, or, in a lesser degree, of other viscera, must, even when not specially severe, be looked upon as affording grounds for anxiety, from a prognostic point of view.

Fourthly, as regards the *constitution, age, and sex of the patient*, it may be safely anticipated that in a patient with a good constitution the prognosis will be more favourable than in a person with a feeble or broken-down constitution. Persons whose vital powers are unimpaired will resist disease, and recover under circumstances which would be fatal to other individuals. In

whom, on the one hand, plethoric habits may predispose to acute and rapid changes, or who, on the other hand, by degeneration of tissues may be rendered liable to succumb, and that rapidly, to morbid influences which healthier textures could resist and overcome.

Disease is badly borne by the very young and the very old. In very young children disease rapidly runs its course, favourably or unfavourably. The aged have little power of reaction or of resistance, and disease in them, though less pronounced, more frequently ends unfavourably. In middle life disease may be expected to assume an acute or chronic form.

As a rule, sex has little influence on the prognosis of disease, except that usually diseases of equal severity are more amenable to treatment in females than in males. Nervous symptoms are however more easily developed in women, exaggerating a condition that might not otherwise be unfavourable. Menstruation, pregnancy, parturition, and lactation have all a certain amount of influence, sometimes favourable and sometimes the reverse, on disease in the female.

Fifthly, with respect to *treatment*, a more or less favourable prognosis may be founded upon the fact that the patient can enjoy all the advantages afforded by rest, diet change of climate, &c., which may not be available under other circumstances for like cases. It is well known that there are some remedies which have a specific effect upon certain diseases, as quinine upon intermittent fever, mercury in some forms of syphilis, iodide of potassium in certain stages of the same disease, and colchicum in gout. In such cases a much more favourable prognosis can, of course, be given than in those for which no such remedies are known to exist. Experience tells us that favourable results follow in many other cases in which suitable though not actually specific remedies can be applied.

Taking into consideration, then, the above conditions—the nature, the intensity, and the seat of the disease; the constitution, the resisting-power, the age, and the sex of the patient, and the possibility of applying suitable and efficient remedies—we are able, in a large number of cases, to arrive at an accurate conclusion as to what the course and result of a disease will be.

DIFFICULTIES OF PROGNOSIS.—Still, to arrive at an accurate prognosis is often very difficult. Disease is not always identical in its character, nor definite in its progress or results. The constitutions of individuals vary, and it is often very difficult to measure their powers of resistance. Remedies, too, vary in their action and their operation, and sometimes we are deceived in the best-founded conclusion as to the results that they will accomplish. There are few physicians who cannot recount the errors of prognosis made by themselves or by their colleagues. Many persons now live who had been doomed to die, and many persons have died whose death was not anticipated. It is the duty of the physician, when asked for his opinion, to state it honestly, but with great discretion, and in general with as much hope as is fairly admissible. He must be guarded as to the manner in which his view is communicated to the patient, for there are many individuals whose temperament is such that the

progress of their disease would be greatly influenced for good or for evil by the expression of a favourable or of an unfavourable opinion. At the same time, the physician must avoid deceit, and if there be risk or danger in communicating an unfavourable prognosis to the patient, he must at least communicate it to some judicious individual amongst the patient's friends. Altogether too much caution cannot be exercised in stating, in any obscure case, what its progress and result will be. There are many cases in which the medical attendant will be justified in replying that he is a physician, and not a prophet. He cannot always foretell results, his aim and object ever being to mitigate the patient's suffering, to prolong life, and to cure the disease if possible. It is full often to profess or to do more than this is beyond his art.

R. QUAIN, M.D.

DISEASE, Symptoms and Signs of.—When disease affects any of the functions or structures of the body, it produces certain altered actions or changes, which, when observed during life, become evidences of its presence and often of its nature, and which then are called the symptoms and signs of disease.

The terms *symptom* and *sign* are often used synonymously, though the derivations of the words are by no means the same. *Symptom*, according to its derivation (*συμπτωμα* = a coincidence) means simply a *coincidence*, that is to say, it coincides with the presence of certain phenomena. The term *sign* (from *σημα*) is more distinctive, and seems more directly to point to some special or peculiar condition. Recently, however, an attempt has been made to give a more special meaning to these terms. *Symptom*, more especially if it be characterised by the prefix *vital*, is intended to refer to modifications of functions, or to such *subjective* phenomena as we can learn from the patient's account of his feelings. On the other hand, the term *sign*, more markedly with the prefix *physical*, indicates those morbid changes which are *objective* or may be recognised by the senses of the physician, assisted by other appliances.

It would possibly be well if the meanings of the words—*symptoms* and *signs* of disease—as above stated, were to come into general use; but there are many difficulties in the way. For example, if the ear be applied to the chest in the case of incompetence of the aortic valves, we hear a murmur, and we say that there are 'physical signs' of aortic valve imperfection, but the locomotive pulse and its peculiar beat, which by many be called a 'symptom' of incompetence of the aortic valves. It is therefore extremely difficult to draw the distinction between the terms *symptom* and *sign*.

By whatever name these phenomena may be called, we must rely upon them as the means by which we are enabled to form our diagnosis. The more accurate and complete our knowledge of the functions of the body and of its component parts, and the more capable we are of interpreting, with all the completeness possible, the changes produced by disease, the more accurate will be our diagnosis as to its presence and its nature. How these phenomena may be best observed will be found discussed under the articles on **DISEASE, Diagnosis of, and PHYSICAL EXAMINATION.**

R. QUAIN, M.D.

DISEASE, Terminations of.—The termination of a disease must be regarded both from a *pathological* and from a *clinical* point of view. Each pathological process or condition has modes of ending peculiar to itself, but it is beyond the province of this article to discuss these at any length, and one or two illustrations must suffice. Thus, inflammation may terminate by resolution; by the formation of different effusions or exudations; or by exuding suppuration, softening, induration, ulceration, or gangrene. Fever, if it end favourably, may terminate by crisis, lysis, or a combination of those modes, or in an irregular fashion. An effusion of blood may remain more or less altered, may undergo organization, may soften and undergo a puriform change, may form a cyst; or may be altogether absorbed.

The *clinical* terminations of diseases are highly important, and demand more consideration. In the first place, a disease frequently terminates in the *death* of the patient. This event may take place suddenly or very rapidly, from the occurrence of some serious lesion or of grave functional disorder of an organ essential for carrying on the phenomena which constitute life. In other cases death is the termination of a more or less acute illness, either affecting a person previously in the enjoyment of good health; or, what is not uncommon, being the consummation of a chronic malady, which has existed for a longer or shorter period. In still other instances, death is a slow and chronic process, the patient gradually sinking, several causes and morbid conditions often ultimately contributing to the fatal event. The modes in which death occurs are described elsewhere, and therefore need not be discussed in this article. See **DEATH**, Modes of.

In the next place a large proportion of cases of disease end in *complete and entire recovery*, the patients being restored to their previous state of health, and no organic mischief established. This result may be expected in most of the ailments or functional disorders which are of such common occurrence, provided proper treatment is carried out. Again, the great majority of cases of acute disease terminate in *incomplete recovery*, taking them in the mass, though several affections of this class, when they do not prove fatal, are liable to leave behind them more or less serious deterioration of the general health, or even actual organic disease. In this class of cases, when recovery does ensue, it is usually only after a more or less prolonged period of convalescence. Chronic complaints, if they are of a structural nature, cannot in most instances end in complete recovery, although to all appearance the patient may often be quite restored. Even in these cases, however, an actual cure may sometimes be effected, and that after a disease has had a prolonged duration. This is illustrated by several chronic skin-affections, syphilis, and chronic inflammation of mucous surfaces. Or it may happen that the patient recovers perfectly, only with the destruction of some structure which is not essential to life, such as the lymphatic glands.

Thirdly, *partial or incomplete recovery* is a very common mode of termination. This is observed in many cases of acute disease, where

either the patient remains permanently in a state of general ill-health, without any actual structural lesion being discoverable; or some positive organic affection has been established, of which phthisis remaining after acute pneumonia, or cardiac disease following acute rheumatism, afford apt illustrations. An attack of an acute malady may also serve to bring out some latent constitutional predisposition; or may leave the patient in such a condition that certain so-called constitutional maladies are readily originated from slight causes. Partial recovery, amounting often to very marked improvement, may take place in many serious diseases of a chronic nature. This is illustrated by numerous cases of pulmonary consumption, in which disease great improvement is often observed, not only as regards the symptoms, but also in the local lesions, so much so that patients not uncommonly regard themselves as cured. Again there are some complaints in which apparent recovery is brought about, but a tendency to recurrence remains, either without any obvious reason or from slight causes. Such affections are exemplified by ague, asthma, neuralgia, intestinal catarrh, bronchitis, and certain skin-diseases. As instances of incomplete recovery may be also mentioned the cure of some prominent symptom or symptoms, while the disease which originates these phenomena continues unaltered. Thus, it may be possible to get rid of ascites, which the patient regards as the disease from which he suffers, while cirrhosis of the liver, upon which the ascites depends, is a permanent condition, extensive dropsy and other symptoms associated with cardiac diseases may also be got rid of, while the organic mischief still remains. Sudden lesions may terminate in partial recovery. For instance, a case in which a sudden hemorrhage into the brain has occurred, attended with marked apoplectic and paralytic symptoms, not uncommonly improves remarkably in course of time, the clot being more or less absorbed. Some complaints, which are usually sudden in their onset, may apparently be recovered from completely, but sometimes set up conditions which ultimately lead to permanent disease. Thus the passage of a gall-stone or of a renal calculus may excite such irritation as to cause an inflammatory process to be set up, which may induce permanent mischief, such as closure of the bile-duct or of the ureter in the several instances, and the effects may not be perceptible until a considerable interval has elapsed.

Lastly, it must be remarked that some affections can hardly be said to have any termination. They continue during the life of the individual, perhaps interfering but little or not at all with the health, or at all events not in any way contributing to the death of the patient, when that event does happen. This applies to many of the ailments from which people suffer; as well as to many chronic organic diseases not in themselves serious or giving rise to any important symptoms, and not implicating structures essential to life. **FREDERICK T. ROBERTS.**

DISEASE, Treatment of.—This term has reference to the means by which disease may be

prevented—*prophylactic*, or *preventive* treatment, or its effects counteracted when it occurs—*remedial* or *curative* treatment.

1. *Preventive treatment* will be found discussed under the heads—CONTAGION, CLIMATE; DISEASE, CAUSES OF; DISINFECTION, MALARIA; PERSONAL HEALTH, PUBLIC HEALTH, &c., as well as in the several articles treating of special diseases. It is therefore unnecessary to say more upon the subject in this place.

2. *Curative treatment*.—Bearing in mind that disease is a deviation from health in the functions or component materials of the body, it must be remembered that there is in organized bodies a tendency to maintain their healthy function and structure and in case of disease or injury to recur to it. This is especially manifest in the lower types of animals, which when mutilated are capable of resuming more or less completely their original form, to the extent even of the restoration of parts that have been lost. In man and the higher animals this power of complete restoration is confined to the elementary cells and least complex structures of which the body consists, the more complex tissues are not reproduced, nor are lost parts restored. There is, however, in man, as in all organized beings, a tendency to rectify deviations from health, and to restore the organization to its normal condition. To remove or subdue the causes of disease, and to aid this restorative power in the establishment of healthy function and structure is for the cure of disease the most philosophical indication that can be adopted. But our knowledge of disease and of remedial agents is not sufficient to enable us always to carry out these principles. As the treatment of disease has been directed sometimes to the one object and sometimes to the other, frequently to neither, it has given origin to a great variety of systems or methods of practice. Thus in the earliest history of the healing art, means the most diverse were used for the relief of suffering. Sometimes the suffering or the disease yielded whilst these means were being employed, and it was concluded, on very insufficient grounds, that these agents had 'cured the disease. Persons who had felt, as they supposed, the beneficial effects of these particular remedies, communicated them to others as the result of their experience, and thus was established what has been known in Medicine as

Empiricism.—This mode of practice has its advantages and its disadvantages. When aided by accurate knowledge and discrimination it often leads to satisfactory results, and many remedies suggested by experience, and that alone, are now found to be in accord with our more advanced scientific knowledge, take, for example, the use of mercury in syphilis, which though long used empirically, is now known to act by its control over the nutrition of young cellular growths. So also with respect to quinine and other remedies of now established usefulness. On the other hand, mere empiricism, when vaguely applied, taints and damages to this day the treatment of disease. It is this practice which, for example, suggests opium to quiet a cough or a colic, without reference to the cause of the one or the other, and when an expectorant or a purgative would have been the suitable remedy, and it is

this empiricism which does such harm in the hands of amateur practitioners, leading them to recommend for the relief of symptoms remedies which they supposed had relieved like symptoms in other cases, however different the real nature or causes of these symptoms may have been.

Rational Treatment.—On the other hand, modern science endeavours to take cognizance of the nature of disease, and also of the specific action of remedies, it seeks to counteract the operation of the one by the influence of the other. This constitutes the rational treatment of disease. To extend this system should be the object of the scientific practitioner. On the one side, it is his duty to study the nature of disease itself, its causes, and their effects; on the other, to study the action of various agents on the living body in health and in disease, and if possible to trace how far the one is capable of combating and subduing the other. This study of scientific therapeutics is of comparatively recent date, and is now pursued with great zeal. The results already arrived at are alike satisfactory and encouraging. As rational treatment becomes more firmly established, scientific medicine will take a more elevated and nobler position. The modes or methods by which the two great principles just alluded to, the foundations as they are of the healing art, have been applied are extremely various, and, although these different methods may be traced to the one or to the other, they have received distinctive names, according as they are marked by some special characteristic. A few of these modes of treatment may be briefly enumerated.

1. *Expectant treatment*.—This mode of treatment is founded on the principle that the restorative power should be allowed entire freedom of action, the practitioner neither assisting nor interfering with its operation.

2. What is called *Homœopathic treatment* would by some persons be included under the preceding head. It proposes to treat disease by giving in infinitesimal doses substances that are supposed to be capable of producing a diseased condition like that which they are intended to cure. It may be described in the words of Molière, who wrote long before Hahnemann, the inventor of homœopathy, as *l'art d'amuser le malade pendant que la nature guerit*. There is no doubt that in this and in similar methods of treatment, the imagination plays an active and useful part.

3. *Palliative treatment* consists simply in the adoption of means which are calculated to soothe, and to lessen suffering, and thereby to prolong life when the cure of disease is not possible.

4. *Stimulant treatment* is founded on a doctrine which regards most forms of disease as associated with or dependent on a lowered state of the vital powers, and which teaches that in such cases the free use of stimulants is the practice most to be relied on. See *STIMULANTS*.

5. *Antiphlogistic treatment* is the converse of the preceding. It recognises in many forms of disease increased nervous excitement and vascular fulness, which are to be remedied by depressing agencies, such as low diet, bleeding, purgation, &c. See *BLOOD, AUSTRICTION OF, AND DEPLETION*.

6. *Purgative, diaphoretic, or otherwise eliminative treatment* aims at removing by the

intestinal mucous membrane, by the skin, or by the secreting glands respectively, certain morbid matters; and thus allowing the restorative power of the system to operate more efficiently. *See* Purgatives, &c.

7. The *Water cure*, including baths, acts partly on the principle of elimination, partly by exerting a tonic influence. *See* BATHS and HYDRO-PATHY.

8. *Revulsive treatment* acts by producing counter-irritation by means of blisters, setons, issues, and the like. *See* COUNTER-IRRITANTS, REVULSIVES, &c.

9. *Dietetic treatment* constitutes a greater or less portion of all modes of treatment. It implies a reference to the kind of food which is adapted to the circumstances in which the patient is placed, and which is suitable in the form of disease from which he is suffering. *See* DIET.

10. The treatment by *Climate* operates more or less by removing the patient beyond the region of noxious influences, and placing him in circumstances which promote healthy action of the several functions.

It is well known that under these several and varied modes of treatment disease may yield and patients may get well. Hence it has been said that as different means are made use of to obtain a single result, the treatment of disease can never be absolutely scientific. Phthisis is pointed out, for example, as a disease which one person seeks to relieve by cod-liver oil, another by climate, a third by tonics, a fourth by sedatives, a fifth by attention to the digestive organs, and a sixth by counter-irritation. We need scarcely say that the disease bearing the name of phthisis is an aggregate of phenomena or conditions, the relief of any one of which may lead to the amelioration of the others. Thus the general health might be improved by climate, and with it all the other symptoms. Cod-liver oil, with remedies calculated to improve the digestion, may lead to healthy nutrition, and thus to mitigation of all the symptoms. The like remark applies to the other agencies mentioned. The treatment of disease must not, then, be condemned as unscientific because it cannot remedy a variety of morbid states by a single agent, but would aim, on still strictly scientific principles, by different agencies to overcome disease the effects of which are manifested in different forms.

In conclusion, it may be repeated that the end and aim of the practitioner should be, if possible, firstly, to discover the cause or causes on which the disease depends, and to remove or counteract them if practicable; and, secondly, to endeavour, by every available means, to restore to health the functions of the body, and with that object to guide and assist Nature, but never to thwart her operations. R. QUAIN, M.D.

DISEASES, Types and Varieties of.—In the case of many diseases more or less distinct varieties are recognised, which in some instances constitute well-defined types. It is important to understand the precise significance of these terms in different cases.

In the first place the varieties of a particular affection may be founded upon diversities ob-

served in its *etiological history*. Thus, according to the intensity of the symptoms and their duration, a large number of complaints are, as has already been pointed out, divided into acute, sub-acute, and chronic varieties. Again, many diseases, while presenting in the majority of cases a certain group of symptoms, upon which their general clinical description is founded, exhibit striking differences in the exact nature of the phenomena observed, as well as in their gravity, when the mass of cases is taken into account, and on these differences *varieties* or *types* are founded. This is well exemplified by some of the acute specific fevers, such as typhoid fever, scarlatina, measles, and small-pox. Of these affections several varieties are described, dependent upon the severity of the symptoms, the nature of those which are most prominent, or the characters of the eruption.

In the next place, the classification of a disease into varieties may be founded upon a *pathological basis*. For instance, pulmonary phthisis may arise from different morbid processes, and many attempts have been made to arrange the cases of this disease into corresponding groups. Illustrations of these pathological varieties are also found in the different forms of cancer; varieties of pneumonia, of laryngitis, and of fatty disease of the heart; and in the classification of serous inflammations according to their morbid products, such as fibrinous, serous, purulent, &c. Again, such a pathological condition as dropsy or fever may be divided into varieties. Thus dropsy is arranged according to its situation and distribution, as anasarca, ascites, &c., or according to its pathological cause, whether cardiac, pulmonary, hepatic, &c. Fever is recognised as having several important types, founded upon its intensity, its course, and the exact nature of the phenomena accompanying the pyrexial state.

Another division of a disease into varieties is *etiological*, the cases being grouped according to their causation, either the immediate pathological or the more remote exciting causes being employed as the basis of division. Thus we have the different forms of meningitis (simple, tubercular, rheumatic, &c.), the etiological varieties of pleurisy or peritonitis (idiopathic, traumatic, perforative, tubercular, secondary, &c.); those of joint-inflammation, (simple, rheumatic, gouty, scrofulous, &c.), or those of intestinal obstruction. Etiological varieties are often at the same time characterised by differences in the pathological results and products. Lastly, it must be mentioned that sometimes a certain *group of symptoms* is summed up for convenience under some single term, which symptoms really depend upon very different morbid conditions and causes; and therefore it often becomes necessary to classify affections thus named into varieties. Dyspepsia, neuralgia, apoplexy, epilepsy, and paralysis will afford illustrations of such an arrangement.

FREDERICK T. ROBERTS.

DISINFECTANTS. *See* DISINFECTION.

DISINFECTION.—*SYNON.*: Fr. *Désinfection*; Ger. *Desinficiren*.

DEFINITION.—Disinfection, in the proper sense

of the term, means any process by which the contagium of a given disease may be destroyed or be rendered inert.

Disinfectants, however, are used in practice for several objects, and in consequence the term has often been vaguely applied to the use of heat or chemical means for preventing the generation or for the destruction of noxious agents, whether products of specific disease or not. In this vague and erroneous sense disinfectants have been confounded with *deodorants*, which merely cover or destroy offensive odours without affecting the contagia, and with *antiseptics*, which 'are fatal to the growth and multiplication of microzymes.' Following the line indicated by Dr. Baxter in his valuable report on an experimental study of certain disinfectants, it is necessary to distinguish—

1. The true meaning of the word—that of acting on the specific poisons of communicable diseases in such a way as prevents their spreading

2. That of acting upon organic substances in such a way as renders them less liable to undergo molecular change and decomposition, whether spontaneously or under the influence of catalytic agents, as in the case of emulsin upon nivalginin, or under the influence of living organisms, such as are connected with fermentation and putrefaction. Examples of this kind of action are seen in salting meat, and in preserving small animals in weak solutions of carbolic acid.

3. That of preventing or arresting decomposition by killing the torula associated with fermentation in slightly acid media, or the bacteroid organisms associated with putrefaction in neutral or alkaline media. Properly speaking, this is the action of an antiseptic, but the relative power of disinfectants has been largely estimated by their efficiency in this respect, partly, no doubt, because antiseptic power is desirable in a disinfectant, but chiefly because it is so difficult to submit disinfectants to their proper test by experimenting upon contagium.

4. That of the destruction of the noxious products of the metabolism of dead organic matter, however brought about. These products consist chiefly of gases or vapours, many of which such as sulphurited hydrogen, ammonia, and sulphide of ammonium, are easily destroyed by appropriate agents, even when used in a very dilute state, and success in this respect is no proof of the value of a disinfectant in its true sense, though the power of destroying such emanations is possessed by almost all disinfectants of practical utility.

MODE OF ACTION.—The manner in which disinfectants are supposed to act is very various. Some, such as permanganate of potassium, ozone, and oxygen, set free from water by chlorine, oxide organic matter. Others, such as sulphurous acid, withdraw oxygen, and have a reducing influence; or, like chlorine, may combine with hydrogen and remove it, or form substitution-compounds. Those of a fourth class, such as chloride of zinc and some other metallic salts, are supposed to owe their activity to the power which they possess of coagulating albumen or combining with it. Another class, of which carbolic acid is the type is supposed to arrest

molecular changes, whether they be those necessary for vital manifestations or for decompositions. And finally, the mineral acids are supposed to be efficacious, in part, at least, because they alter the reaction of the media containing contagia. Most disinfectants act in several of these ways.

GENERAL REMARKS.—It has been proved that the contagia of several diseases must consist of minute solid particles, for they are neither soluble, nor diffusible, nor volatile, and we may infer that all other contagia are particulate likewise. A characteristic of contagium, due to its particulate nature, is that dilution lessens the chance of infection, but has little effect upon the case if the disease be taken. There is either no effect at all, or a full specific effect. Contagium particles are apt to exist as clouds in air, water, or milk, instead of being equally distributed throughout, and this bears upon practical disinfection. The particulate and non-gaseous form of contagium floating in the atmosphere prevents it from being absorbed by any liquid or solid disinfectant which does not wash or come into intimate contact with every portion of the air, and as this is impracticable, infected air can only be purified by gaseous disinfectants, such as sulphurous acid or chlorine. Disinfectants of this kind, to be effective, must be present in such a quantity as is incompatible with the existence of human beings. From this it follows that saucers of disinfecting fluids, or irritating vapours and gases in the sick-room are merely a useless annoyance to the patient, except in so far as they may be desired as deodorants. The best method for dealing with infected air is to replace it by ventilation, especially by means of *ventilating* open fire-places. The proper use of volatile disinfectants is the purification of walls, ceilings, and inaccessible places, and for this purpose, if possible, enough should be used to saturate the atmosphere, remembering that the virulent particles are most likely protected by being buried in a bit of epithelium or surrounded by an albuminous envelope.

The nature of the medium in which contagious particles are suspended has the most important bearing upon the selection of a disinfectant. The presence of albumen is found to protect septic germs to a considerable extent against the action of permanganate of potassium and chlorine, but has little or no influence upon the action of sulphurous acid and carbolic acid. Dr. Baxter gives reasons for believing that the comparatively uniform quantitative action of carbolic acid upon contagia and septic microzymes, as compared with the striking differences between the disinfectant action of chlorine and permanganate upon contagia on the one hand and septic microzymes on

* Though disinfectant or antiseptic gases of such strength as can be tolerated in the sick-room are utterly inept as regards useful effect upon contagium, it is just possible that they may be of service in destroying or rendering ineffectual of change the organic matters evolved from the skin and lungs, which are always very noxious, and may be especially so in disease. These organic matters are necessarily more or less re-breathed unless the patient be placed in a current of air. If ventilation sufficient to prevent all odour cannot be provided, then some gas, such as chlorine or ozone, that will destroy the cause of the odour is certainly desirable.

the other, is chiefly or entirely due to differences in the media in which the respective particles are suspended, and not to differences in resisting power possessed by the particles themselves. This points to an important advantage enjoyed by substances like sulphurous acid or carbolic acid, which appear less influenced by the nature of the medium, and also shows the necessity of thoroughly mixing disinfectants with liquids or substances to be disinfected. The alkaline or neutral character of virulent substances led Dr. Dougall to select dilute hydrochloric acid, which has little action upon lead soil-pipes in the cold, as the best disinfectant for excreta.

A cardinal principle in disinfection is that it should be carried out at the source, or as near the source of the contagium as possible. Inunction with lard, with carbolised oil (1 to 40), or with glycerine, to clog epithelial scales, and regular washing and change of clothing, will do much to protect the purity of the air against contagium proceeding from the skin in such diseases as scarlet fever and small-pox. One of ethereal solution of peroxide of hydrogen to 8 of lard is an excellent application for the skin in typhus. Discharges from the mouth, nose, and bowels, as well as the urine, should be received in vessels containing disinfecting solutions to cover them and give protection to the air; and then larger quantities, or more concentrated solutions, as the case may be, should be thoroughly incorporated with the discharges before they are removed from the original vessels.

Of all agencies for preventing the spread of communicable disease, cleanliness is one of the most important. Facts have been adduced pointing to the conclusion that filth, when an ongoing change of a fermentative or putrefactive nature, is in a condition the most conducive to the extension of infectious disease. Pending the removal of accumulations of dirt, and for the protection of workmen, fermentation may be delayed by the application of crude carbolic acid, chloride of zinc, or bichromate of potash, used in moderate quantity as antiseptics, and the whole accumulation might then be earthed over if it had to remain any time. For real disinfection the large quantity required and the mixing necessary would be prohibitory.

The ultimate fate of contagium is to be destroyed by putrefaction, and this appears invariably to destroy its specific infective power. In certain cases where real disinfection is impracticable, as in dealing with the accumulation of manure and litter from a number of animals suffering from cattle-plague, the natural processes may be hastened by stacking the material so that it shall 'heat,' or may even be destroyed by spontaneous combustion. Certainly putrefaction should not be delayed by small additions of disinfectants, which cannot accomplish the destruction of all noxious matter present.

SPECIAL DISINFECTANTS. 1. *Heat.*—Heat, dry or moist, is perhaps the best disinfectant we possess. The experiments of Drs. Henry, Baxter, W. Roberts and others have shown the effects of this agent upon vaccine, malignant pustule, septic micrococcus, scarlet fever, plague, &c.

High temperature and length of exposure are, to a certain extent, mutually compensatory, but it appears that a temperature below 140° F. (60° C.) will not disinfect vaccine even with long exposure. Tyndall points out that some germs seem to be in a dormant condition, in which they resist the action of heat unless applied very long or intermittently, so as to start their vitality into growth, when they are easily killed. Experimental facts show that excessive temperatures are as unnecessary as dangerous in practical disinfection. It is extremely improbable that any contagium can withstand a temperature of 220° F. (104.5° C.), maintained during two hours. When contagium is shielded by thick material, into which heat penetrates slowly, the time necessary to reach the disinfecting temperature may be long, and hence the necessity for spreading clothing and opening out bedding in special hot-air chambers, where the heat ought not to be less than 220° F. (104.5° C.), nor more than 250° F. (121.1° C.). Hot-air chambers are usually built of brick, and are furnished with wooden supports for clothing, which should not come in contact with metal.

Dr. James B. Russell, Medical Officer of Health for Glasgow, has communicated to the writer the most important fact, that at the Infectious Diseases Hospital of that city no further disinfection of the linen and clothing of the patients is carried out than is afforded by the boiling, washing, &c., required in the judgment of the washerwomen to cleanse and dress the clothing; and yet a continuous careful scrutiny has failed to discover a single case of disease propagated by such clothing. It is probable that soda is used in the boiling, in some cases at least, and the extreme softness of Glasgow water doubtless helps by its osmotic and dissolving power.

2. *Carbolic Acid.*—A solution of this substance of the strength of 5 per cent., or 1 in 20, is the only one fit for use in disinfection. For steeping fine clothing a solution should be made from crystals. The solution generally useful is that obtained by making up one gallon of crude 80 per cent acid to sixteen gallons with water. To disinfect a suspected liquid, an equal volume of one of these solutions is needed. The results of the experiments of Baxter and others prove that 'no virulent liquid can be considered disinfected by carbolic acid unless it contain at least 2 per cent. by weight of the pure acid.' A preparation called *Douglas's Powder* contains carbolic acid, but is inferior to the pure kinds, though safer and more applicable in many cases to prevent odour. Judging from the light of experiments, carbolic acid vapour is quite useless, though clinically Mr. Crookes and Mr. Hope thought it of use in cattle plague, but the animals and surroundings were drenched with liquid acid or solution. Though carbolic vapour appears impotent as regards effect upon contagium it will preserve the freshness of a bit of meat suspended in it for months. Very small quantities of the liquid acid mixed with organic fluids enables them to remain fresh and resist decay for a long time. So little as one-fifth per cent. preserves milk. It is obvious then that small quantities of this disinfectant, instead of destroying contagium, may actually preserve its

activity, when otherwise it would have succumbed to the action of natural agencies. This danger may accompany the limited use of any disinfectant that has a 'pickling' or preservative action in small quantity. Owing partly to the volatility of carbolic acid, which removes it in time, and partly to the peculiarity of its action, another danger attends its use in anything short of full strength and full doses when applied to kill contagium. The acid may, for a time, deprive the contagium of its infective power without permanently abolishing it, and the virulent properties may be regained whenever the acid has evaporated. This has been proved experimentally by Dr. Dongall, of Glasgow, who found that vaccine mixed with carbolic acid (1 in 50) regained its infective power after 10 days' exposure to the air.

Carbolic acid coagulates albumen when in sufficiently strong solution, while it restrains putrefaction, and limits the growth of low forms of animal life. It decomposes potassium permanganate, and therefore cannot be used in conjunction with this agent or with chlorine. Though it does not destroy sulphuretted hydrogen, it is a good deodorant in some cases. When Demonstrator of Anatomy to the University of Edinburgh, the writer experimented on a large scale with different substances for removing odour from the hands of the students, after working in the dissecting-room, and found that a 1 per cent. solution of carbolic acid is superior in efficiency to permanganate, even when strong enough to stain the skin, and is also preferable to chloride of lime. In this connection it is worthy of remark that the 'septic ferment' connected with septicæmia, erysipelas &c., appears to be destroyed by rather less carbolic acid than vaccine requires.

3 Sulphur Dioxide.—The aqueous solution of this substance contains sulphurous acid. Baxter's experiments show that it is the most potent volatile disinfectant known, and as it is very soluble, and is little affected by the presence of albumen, it is also powerful in the disinfection of liquids. It destroys sulphuretted hydrogen thus, $\text{SO}_2 + 2\text{H}_2\text{S} = 2\text{H}_2\text{O} + \text{S}_2$, and combines with ammonia. A strong solution of sulphurous acid is sold, but is difficult to use, on account of its suffocating odour. The solution can be made by deoxidizing hot concentrated sulphuric acid with copper-turnings or charcoal. For aerial disinfection the best plan is simply to burn sulphur in very large quantities. This disinfectant forms sulphites, and is a reducing or deoxidizing agent, in the first place, for it unites with the oxygen of many compounds to form sulphuric acid, but it may give up oxygen, and when mixed with much vegetable matter the sulphur may come off as sulphuretted hydrogen. Sulphur dioxide and chlorine as well as this substance and permanganate of potash, mutually destroy each other, and therefore should not be used together. Sulphur dioxide destroys the activity of dry vaccine on points very rapidly, and even when much diluted stops the amoeboid movements of living cells, kills vibrios, and acts deleteriously on vegetation. Whether chlorine or sulphur dioxide be chosen, it is desirable that the space to be disinfected should be kept satu-

rated with the gas for not less than an hour. 'A virulent liquid cannot be regarded as certainly and completely disinfected by sulphur dioxide, unless it has been rendered permanently and strongly acid. The greater solubility of this agent renders it preferable, *enteric paribus*, to chlorine and carbolic acid, for the disinfection of liquid media' (Baxter). According to Baxter's experiments, a larger percentage of sulphur dioxide than of carbolic acid is required for the disinfection of the virus of infective inflammation, but a smaller percentage for other contagia. Sulphur dioxide preserves meat and other substances, when in closed vessels, for very long periods. It bleaches vegetable colours, attacks iron, and is absorbed by cloth and leather—facts to be remembered in practical disinfection. 1 lb of sulphur, when burned, produces 117 cubic feet of sulphur dioxide gas.

4 Chlorine is most easily obtained from chloride of lime or bleaching powder, by adding hydrochloric or sulphuric acid. Exact proportions cannot be stated, as the value of the bleaching powder varies, but rather more acid than equal parts of bleaching powder and strong hydrochloric acid may be taken. The acid should be diluted before use. Another method is to pour strong hydrochloric acid upon heated binoxide of manganese, this method of disinfection is impracticable compared with burning sulphur. For deodorizing water-closets, some crystals of potassium chlorate may be thrown into a wide mouthed bottle containing dilute hydrochloric acid. Eucchlorine comes off gradually, and is both more effective and more agreeable than chlorine. The most marked character of chlorine is its strong affinity for hydrogen, which enables it to break up compounds containing that body, and to set free in a latent or active state the oxygen combined with hydrogen in water. It is, therefore, one of the most universally applicable and powerful deodorizers in existence. Direct experiment shows that 'there is no security for the effectual fulfilment of disinfection short of the presence of free chlorine in the virulent liquid, after all chemical action has had time to subside.' Chlorine is soluble in water to the extent of 2½ volumes in one, and this solution may be used for disinfection. When merely used as a deodorizer, enough eucchlorine may be expelled from moist chloride of lime by the carbonic acid of the air for most purposes.

5 Permanganate of Potassium.—This substance is non-poisonous, and is a good deodorant, especially for the emanations from organic bodies. It is, moreover, free from odour, and its aqueous solution shows, by loss of colour, when it is exhausted. It is a very suitable deodorant for the sick room, as, when dissolved in water and a large surface of the solution exposed to the air, it will absorb gases to some extent. Contagium being non-gaseous, is not affected, unless in contact with the solution. Permanganate of potassium is a true disinfectant, oxidizing and destroying contagia as well as putrid matters, but the quantity required and the price render its use almost impossible, for enough permanganate has to be used to destroy the medium or vehicle bearing contagium as well as the contagium itself. Condy's fluid is

a solution of this substance in water. *When permanganate of potash is used to disinfect a virulent liquid containing much organic matter, or any compounds capable of uniting with the permanganate, there is no security for the effectual fulfilment of disinfection, short of the presence of undecomposed permanganate in the liquid, after all chemical action has had time to subside' (Baxter). When the virulent liquid or matters are small in quantity, permanganate solution forms a capital receptacle, and may stand by the bedside as a deodorant till required as a disinfectant. The safe rule in employing permanganate as a disinfectant is to add it and mix till the colour is retained. Permanganate has no effect in restraining the appearance of bacteria, or preventing the onset of putrefaction.

6. *Acids*.—The mineral acids and glacial acetic acid have all disinfecting power when used in sufficient quantity; but, except sulphurous acid, there are serious difficulties in the way of their use, and we have better disinfectants. Hydrochloric is inferior to chlorine as a gaseous agent; but the solution is extremely cheap, and is useful for disengaging chlorine, as well as for employment as a disinfectant. Chromic acid, which has remarkable power in preventing putrefaction and killing microzymes, is too dear to be used outside the laboratory.

7. *Nitrous Acid*.—Nitrous acid can be easily disengaged as a gas by putting lumps of copper into nitric acid, or pouring nitric acid upon sawdust or starch. It is the best deodorant for the dewhouse, and, without doubt, it is a vigorous disinfectant, but is too dangerous for ordinary use, as it may easily be breathed in quantity sufficient to cause fatal bronchitis.

8. *Chloride of Lime*.—Bleaching powder gives off chlorine easily, and this probably explains its disinfecting power. It is very cheap and manageable, and hence of much importance.

In regard to the agents hitherto considered, we have more or less of the sure light of direct experiment upon contagium, but the claims of the following and a legion of other substances asserted to be 'powerful disinfectants, of which it is impossible to speak too highly,' rest entirely upon chemical theories, or the opinions of physicians, or upon their power of coagulating albumen, or of delaying or preventing putrefaction and fermentation, or of deodorising. It will be scarcely necessary to do more than enumerate the best, as follows:—

9. *Metallic Salts*, including—*a. Bichromate of Potash. b. Sulphate of Copper. c. Chloride of Zinc (Bernett's Fluid)* which can be made very cheaply by pouring hydrochloric acid upon calamine, the native carbonate, or upon zinc. It seems to be the most useful of the metallic salts. *d. Chloride of Aluminium. e. Ferric Chloride*, which, if strong, liberates offensive fumes from animal matters, but is a fair antiseptic and preservative. *f. Ferrous Sulphate. g. The Waste Chlorides*, from the manufacture of chlorine, contain $MnCl_2$, Fe_2Cl_6 , and free HCl , which cost next to nothing, and might be used for larger masses of fifth or drains.

10. *Ozone*.—This body, got by half immersing a stick of phosphorus in tepid water, or

mixing gradually 3 parts strong sulphuric acid and 2 parts permanganate of potassium, oxidises organic matter, and so destroys odours. Terrene and euphratum, a preparation containing terrene, are good deodorants, and give rise to ozone.

11. *Charcoal*.—Charcoal condenses gases within its pores where combustible gases are destroyed by the condensed oxygen. Contagium, unless in water, does not enter the pores, for, being particulate, it is not absorbed from the air as gases are.

PRACTICAL DISINFECTION.—In conclusion a few remarks may be offered as to the modes of carrying out disinfection under circumstances in which it is commonly required.

1. *Clothing and bedding*.—In dealing with the ragged and worthless articles of the poor, local authorities will generally find it most satisfactory to both parties to burn them and replace with new. By such discreet generosity danger is averted, and good-will created, which helps in getting early information and carrying out measures, and so, by shortening epidemics, saves expense. If not burned, clothing may be laked (*see Heat*), or well boiled with soda. Before coming to the washhouse they may steep in 5 per cent. carbolic solution, or chloride of zinc (1 to 240), or chloride of lime (2 oz. to the gallon).

2. *Rooms*.—The foundation for disinfecting rooms is thorough cleansing with soft soap and hot water, which may contain 5 per cent. carbolic acid, but the carbolic solution is not so easily handled. The walls and ceiling should be brushed, and wall-paper removed. Furniture, if iron, is to be washed with carbolic solution, and removed from the room. Textile fabrics should be baked or boiled, or spread out in the room for fumigation, but this is not so effective, and colours are bleached. The chimney, doors, and windows are to be closed, and crevices covered with paper pasted on. Then one or more tubs of water are to be placed in the room, and an earthenware saucer containing sulphur placed over each, supported by a pair of tongs laid across to prevent danger from fire. The sulphur can be lighted by pouring a little alcohol upon it, or by means of a live coal. The usual rule is to use 1 lb of sulphur for each 1,000 cubic feet of space, but this only gives 1.17 per cent. SO_2 to the air, and 3 lbs. is a more satisfactory quantity. The door is to be shut until next day, when the windows and doors are all to be opened, and kept open for twenty-four hours. In white-washed rooms the walls should be scraped, and then washed with hot lime in addition to the fumigation.

3. *Drains, Water-closets, &c.*—Proper drains remove sewage so swiftly and completely, that little or no sewage-gas is formed if ventilation is given. For bad drains carbolic acid, chloride of zinc, or waste chlorides from the manufacture of chlorine are fair palliatives. The excreta from cases of infectious diseases require a very large quantity of disinfectant, which should be applied in a concentrated form before they are thrown into the water-closet or house pipes. When a reliable amount of disinfectant is in these cases sent down the pipes, it is apt to corrode them unless it has been allowed to

expend its energy on the excreta alone in the first place. If small quantities of disinfectants are poured down water-closets it is better to mix them with the after-flush water which fills traps and basins, so that the little energy available may be devoted to the destruction of any slime adhering, or portions of organic matter retained. Permanganate of potash is the most pleasant agent for this purpose, though expensive. Chloride of zinc, from its cheapness and preservative power, is worthy of mention. When there are no water-closets, no excreta in cases of cholera and typhoid fever should be received in a vessel containing half a pint or more of a 1 in 20 solution of commercial hydrochloric or sulphuric acid, and then put along with some chloride of lime into a covered stoneware vessel in the back yard. After a few hours the contents of this vessel may be thrown into the cesspool or upon the midden.

4 **Dead bodies** if putrid or bearing contagium, should be wrapped in sheets wet with 1 in 20 carbolic solution or 1 in 40 chloride of lime, or, if effused, sawdust saturated with one of these solutions should be picked around them.

It is necessary clearly to keep in view the object desired when selecting disinfectants, deodorants, or antiseptics, whether it be destruction of contagium, merely 'pickling' and preserving arresting putrefaction and fermentation, or deodorisation. From all that has been said it is evident that the different 'disinfecting' nostrums, applied as their inventors direct, can have little effect upon contagium, but may have more or less power in the other directions indicated.

DISSECTION. WOUNDS See Post-MORTEM WOUNDS.

DISTOMA (*dis*, double, and *stoma*, a mouth)—*SYNON*: Fluke, *Flascula*, Fr. *distome*, Ger. *Leberwurm*.—A genus of trematode parasites, vulgarly called flukes. The term was founded by Reizius in 1786, but the title *Fasciola*, previously employed by Linnaeus, is the more correct, especially when applied to the common liver fluke, which is an occasional inhabitant of the human body. Nearly twenty instances of the occurrence of this parasite (*Distoma hepaticum* of some writers) in man have been placed on record. Besides infesting the liver, ducts and gall-bladder, it has been found under the skin behind the ear (Fox), beneath the navel (Harris), and in the sole of the foot (Giesker).

Several other species of fluke are known to infest mankind, but with the exception of the Egyptian *amatozoon* (*Ditharzia hamatoha*) none of them are of frequent occurrence. Thus the lancet-shaped fluke (*Distoma lanceolatum*) has thrice occurred, leading to a fatal result in a single instance, whilst the minute *Distoma heterophyllum* has only once been recorded. The large human fluke, sometimes known as Busk's fluke (*Distoma crassum*) had also, until lately, only once been noticed; but, through Dr. George Johnson, the writer has become acquainted with

two more instances of infection from this parasite, and there is some ground for believing that the cases of fluke described by Dr. Leidy of Philadelphia refer to the same parasite. More recently also (*Lancet*, 1875) Dr. McConnell has recorded the occurrence of an undoubtedly new species from a Chinese, for which the writer has proposed the title of *Distoma sinense*. Large numbers infested the ducts of the liver. Professor Leuckart subsequently proposed the term *Distoma spathulatum*. Professor McConnell has also discovered another fluke in man (*D. conjunctum*, Coddard) previously only known to infest the fox and dog. Taken as a whole the human flukes referable to the genus *Distoma* have very little clinical importance, but, since there were striking symptoms in connection with the above-mentioned cases of *Distoma crassum* (affecting an English missionary and his wife during their residence in China) it may be as well to mention that these large parasites individually varying from one to three inches in length, appear to be capable of inducing severe diarrhoea and colic. Their organisation is totally distinct from that of the common fluke. They probably never gain access either to the liver or its ducts (*Proceed. Linn. Soc.*, Feb. 1875.) The administration of emetine, male fern, and other anthelmintics has been unattended with positive results, those specimens that were expelled seeming to have been, as it were, starved out by the patients having been put upon a milk diet, recommended by Dr. Johnson. The missionary and his wife having returned to China were again attacked by *Distoma crassum*. In the spring of 1878, they again consulted the writer in London, not only on their own account, but also on behalf of one of their children, a little girl, who had also contracted the fluke-disorder in China. Flukes have twice or thrice been detected in the eye, but they appear to have been sexually immature worms, referable probably, as Leuckart has suggested, to the *Distoma lanceolatum*. The flukes described by Troutler and Della Chiusa, if genuine, have no clinical importance.

DIURESIS (*dis*, through, and *oûsîn*, I pass water)—A free excretion of urine, whether natural or artificially induced.

DIURETICS (*dis*, through, and *oûsîn*, I pass water).

DEFINITION—Remedies which increase the secretion of urine.

ENUMERATION—The following comprise the most important diuretics:—Water; salts of Potash, Soda, and Lithia; Alcohol, Nitrous Ether, Turpentine, Juniper, Copala, Cantharides, Digitalis, Squill, Tobacco, and Scoparium. The action of diuretics is often aided by brisk purgation, depletion, counter-irritation over the loins, and sometimes by the use of mercury.

ACTION.—The secretion of urine appears to consist partly of mechanical filtration of fluid

through the glomeruli of the kidney, and partly of secretion by the cells of the urinary tubules. The filtration in the glomeruli is increased by anything which raises the blood-pressure throughout the system generally, or in the renal arteries locally. The systemic blood-pressure may be raised by cold to the surface, digitalis, squill, and tobacco. Digitalis, and possibly other drugs have also a local action on the renal arteries, which are more readily affected by some drugs than other arteries in the body. The exact mode of action of the other diuretics is not determined, but common salt, nitrate of potash, urates, and urea increase the flow of urine, even although the pressure in the vessels of the kidney is very low. It is therefore probable that they stimulate secretion by acting on the nerves or cells in the kidney itself.

Uses.—Diuretics are employed to increase the flow of urine, and thus remove water or excrementitious products like urea from the body. They are used in cases of general dryness, or of accumulation of fluid in the peritoneum or pleura. In febrile conditions they are given to aid in the elimination of waste matter. They are also employed in order to render the urine more watery, and thus prevent the deposition of solids from it, and the formation of calculi in the kidney or bladder, or to redissolve such concretions when they are already formed. Digitalis and squill are most useful in dropsy dependent on heart-disease, the other remedies are more effective in dropsy dependent on disease of the kidneys or liver. The action of digitalis and squill is greatly assisted by the addition of a little blue pill, and when the kidneys are much congested or pressed upon from without by accumulation of fluid in the abdominal cavity, diuretics sometimes fail to act until the congestion has been relieved by depletion from the loins or the use of a brisk purgative, and the pressure removed by paracentesis. T. LATHAM BRISTON

DIZZINESS. See VERTIGO.

DOCHMIUS (δοχμος, twisted) — A genus of nematoid worms established by Du Jardin. See SCLEBOSTOMA.

DOTHINENTERITIS (δοθίνη, a pustule and *ερεπον*, the intestine) — A synonym for a form of enteritis, accompanied by an enlargement of the follicles, which causes them to resemble pustules. See *INTESTINAL DISEASES*, of.

DOUCHE (Fr.) — **DEFINITION** — A jet of water propelled against some part of the body through a *douche* or pipe. The size of the jet of water, the degree of its impetus, and its temperature, can all be regulated. A douche differs from simple affusion in its application, being more local, and the force with which it is applied being greater.

APPLICATION AND ACTION — Douches of cold and of hot water, of vapour, and occasionally of gas are employed; but those by far the most commonly used, except where there are hot natural waters, are of cold water.

The immediate effect produced by a cold douche on those who are unaccustomed to it is a feeling of shock, spasmodic shortness of breathing, palpitation of the heart, and some-

times pain in the back of the head. Locally the first effect of a douche is to deaden the sensibility of the part to which it is applied, but if the douche be powerful enough, reaction of the part comes on in about forty seconds. This continues for a time, but if the douche be kept up for three or four minutes, the pulse falls seven or eight beats, the deadening of sensibility returns, and the temperature of the part is greatly lowered, when the douche is withdrawn reaction again takes place. This alternate sedative and stimulating effect, producing emptiness and turgescence of the vessels, quickens the action of the capillaries of the part, and thus favours the transmutation of tissue. The mechanical effect of the force with which the douche is applied must not be overlooked. If great, it produces the highest amount of stimulation, which may almost amount to inflammation.

Different portions of the body have different degrees of tolerance of the douche. Thus the extremities and the head bear it better than the chest, and the chest somewhat better than the abdomen, and the posterior aspect of the body bears it much better than the anterior. Patients soon get accustomed to the cold. Warm douches produce less shock, and are more easily borne, but they are comparatively speaking, little employed in private houses. An alternation of hot and cold douches, known somehow by the name of *Scotch*, is a valuable remedy, in it the hot water rapidly restores the irritability of the part deadened by the cold water, and there is a maximum of action and reaction of the part obtained. Under particular circumstances it may be expedient to use a jet of steam, but this, of course, must be used with caution, and a jet of carbolic acid is sometimes propelled against the eye or ears or the neck of the uterus. What are called *ascending douches* are used for the rectum or the vagina. Douches for the eye and the ear have been used of late years. In a certain sense what the English call *pumping* is a variety of the douche, and the *shower-bath* is in reality merely a multiplication of fine douches. The action of douches is more or less general according to the portion of the body to which they are applied. Thus the application of a douche to the head has the most general action, and that to the spine the next so. In either case it is impossible to limit it very strictly, and there is a certain amount of affusion besides the direct douche. A douche, again, applied to one of the extremities may easily be localised, and a douche may be applied only to one part or to several parts of the body in succession.

Douches merely require a pipe with nozzles of various sizes in connection with a cistern at a certain elevation, or with a pumping machine, and can easily be improvised. Shower-baths can be procured with equal facility. A vapour douche can be got by attaching a pipe to a vessel of boiling water. In the case of the fine douches used for the eye, the water is propelled with sufficient force by the action of a caoutchouc bag worked by the hand. Carbolic acid is practically little used, and only where there is an abundant natural supply of the gas.

Perhaps 50° may be considered the average temperature of a cold douche, and from four

minutes to a quarter of an hour its average duration. The course of douching will probably extend at least over a fortnight. As to the actual temperature of the water, the sensation it produces in the patient depends most on his condition. Thus water of 45° may feel ice-cold to one who has just quitted a hot bath. In like manner a douche of slightly-heated water may appear quite warm when applied to a part cooled by a cold douche. The temperature of a douche should vary according to the condition of the patient.

Uses.—As a general rule we may say that douches are only applicable in cases of chronic disease, that cold douches are most useful in constitutional diseases, and that warm douches, and the alternation of hot and cold, are most suitable in local affections.

The cold douche, when it is employed gradually and with judgment, is found serviceable in chlorotic and hysterical conditions, in hysterical paralysis, and in oversensibility of the skin, with tendency to catch cold, and of late years it has formed a part of the special treatment of phthisis in elevated places. As cold affusion on the head is very serviceable in infantile convulsions, so the application of a douche of cold water to the head is a calumative and hypnotic in maniacal cases. It is, perhaps, not so much used in this way as formerly, as it has, like the shower-bath, come to be considered a sort of punishment to troublesome lunatics. Still it is a valuable agent. Hydropathic practitioners have found douches useful revulsives in congestion of the liver and of the uterus.

Locally douches have been used, but with moderate benefit only, in some cases of skin-affections and of chronic ulcers. Their principal local application, however, is in cases of old sprains, in chronic inflammation or gouty thickenings of joints, in lumbago, in some neuralgias, and in paralysis when it is not too recent. The *Scotch* is far the most effective for these purposes, and there seems to be some evidence of its having been efficacious in threatened labor doules—certainly more efficacious than any other remedy. Douching might be used more extensively in private houses, still, as assistance is always required by the patient, public baths have advantages for their application.

JOHN MACPHERSON.

DRACUNCULUS (*dracunculus*, a little dragon).—A synonym of the guinea-worm. Under this title the parasite was described by Laster (*Phil. Trans.* 1690), and afterwards by Kneuper (1694). Following the latter authority the writer has elsewhere recognised the term as of generic value, but the majority of helminthologists, after Gmelin, prefer to place

FIG. 17.—*Dracunculus Medinensis*. Reduced to $\frac{1}{2}$.

the worm under the genus *Filaria* (*F. medinensis*). The *Dracunculus* was known before the time of Laster, having been described in a remarkable work by Velocius (1674) and by Agatharchidas as quoted by Plutarch. There is

indeed, every reason to believe that the so-called fiery serpents of Moses answer to the dracunculi of Plutarch. The matter is fully and learnedly discussed in Kuchemann's treatise (*Parasiten*, S. 305, also in the English edition, p. 390 of *ay*). See GUINAWORM. T. S. COMBELL.

DRAINAGE. See PUBLIC HEALTH.

DRASTICS (*ῥῥῆς*, I act).

DEFINITION.—Violent purgatives.

EXPLANATION.—The drastics most frequently employed are:—Hellebore, Iodophyllin, Gamage, Elettarium, Scammony, Jalap, and Croton oil.

For action and uses of drastics, see Purgatives. T. LAUDER BRUNTON.

DRIBURG, in Westphalia. Strong Chalybeate Waters. See MINERAL WATERS.

DROITWICH, in Worcestershire. Common Salt Waters. See MINERAL WATERS.

DROPSY (*ῥῥῆσις*, from *ῥῥῆσις*, water, and *ῥῥῆσις*, aspect, appearance)—**SAISON.** Fr. *Hydropisie*, Ger. *Wassersucht*.

DEFINITION.—Accumulation of serous fluid in the subcutaneous cellular tissue, or in a serous cavity.

Dropsy is known by various other names, according to the portion of the body affected. When confined to the subcutaneous cellular tissue it is termed *oedema* or *anasarca*, to the peritoneal cavity, *ascites*. The term is often limited to these two forms of the disease, and exudations similar to that of ascites in other cavities are termed *hydropneumothorax*, *hydrocephalus*, *hydrocrisis*, *hydrocrisis oculi*, *hydrocrisis articuli*, and *hydrocrisis pleuralis*, according as they are contained in the pericardium, ureter, and tunica vaginalis, eye, joint, and pleura respectively.

PATHOLOGY. The accumulation of fluid in the tissues, or in a serous cavity, depends upon more fluid exuding from the blood-vessels than can be taken up by the absorbents. So long as no obstruction to absorption occurs, it rarely happens that more fluid can exude from the blood-vessels than the absorbents can again take up. Absorption is partly carried on by the veins, and partly by the lymphatics, principally, however, by the veins. When venous obstruction takes place, fluid is apt to accumulate in that part of the body from which the blood ought to return by the obstructed vessel. But it does not always so accumulate, for it may happen that the lymphatics are able to absorb all the fluid which exudes from the capillaries, and to return it into the general circulation. Thus it has been found by Ranvier that ligation of the vena cava in a dog does not usually produce oedema of the lower extremities, but if one sciatic nerve be divided in such an animal, the corresponding leg at once becomes oedematous. The reason of this is that so long as the nerve is intact, the lymphatics can absorb all the fluid which exudes from the capillaries, but when the nerve is divided the arteries dilate, more fluid is poured out than the lymphatics can absorb, it accumulates in the tissues, and oedema ensues. This oedema is not due to

paralysis of the limb, but to paralysis of the vessels. For if the sympathetic fibres through which the vaso-motor nerves pass to the sciatic nerve are divided before they join the motor fibres of that nerve in the sacral plexus the power of movement remains unimpaired, but œdema occurs just as if the whole nerve had been divided. If, on the other hand, the motor strands of the sacral plexus are cut before they are joined by the sympathetic fibres, the limb is as completely paralysed as if the sciatic nerve had been cut, but no œdema takes place. Any obstruction to the venous flow will operate in the same way as ligation of a vein, though to a less extent, the effect varying according to the amount of obstruction. Thus regurgitation of blood through the tricuspid valve tends to produce general anasarca, and obstruction to the portal vein by cirrhosis of the liver tends to cause accumulation of fluid in the abdominal cavity.

It has been mentioned how great an influence dilatation of the arteries from vaso-motor paralysis has upon the production of œdema in cases where the veins are obstructed. Arterial dilatation may also produce a local œdema, even when no such obstruction is present, as, for instance, in the tissues around an inflamed part. It has been shown, however, by Winckler, that the walls of vessels in an inflamed part are more permeable, and allow fluids to pass through them more easily than healthy vessels will do. It is probably in consequence of this that we find that a slight stimulus, such as scratching the skin, which ordinarily produces in a healthy person only slight dilatation of the capillaries, and consequently redness of the part scratched, will produce an effusion from the vessels, and local swelling of the part at the point scratched in persons suffering from urticaria. The same thing takes place when the skin is scratched in the neighbourhood of a part stung by a wasp.

But this alteration in the vessels is not the only cause of the œdema, which may occur without any obstruction to the circulation. An alteration in the composition of the blood appears to allow it to permeate more easily into the tissues, and to produce œdema, even when there is no obstruction of the veins. In cases of anemia we find œdema occurring at the ankles, although there is no obstruction to the venous circulation other than that caused by the weight of the column of blood itself. In these cases, however, we have dilatation of the vessels, as is shown by the form of the sphygmographic tracing, and an altered composition of the blood is evidenced by the anæmic look of the patient. The dropsy of scurvy is probably also due to blood-vascular disorder. In albuminuria the altered composition of the blood appears to be the chief factor in the production of œdema, as the pulse in such cases may be hard, evidencing arterial contraction, and not relaxation.

Ætiology.—General dropsy affecting the subcutaneous tissue, the peritoneal cavity, and the internal serous cavities and organs generally, is usually the result of albuminuria, and most frequently of that form which depends on fatty degeneration of the kidney. In cirrhotic disease

of the kidney the loss of albumen in the urine is much less, and the alteration in the composition of the blood consequently is not so great as in the first-mentioned form. The arterial tension also is greater than usual, instead of being less. In the amyloid form the œdema is generally moderate.

The next most common cause of dropsy is tricuspid regurgitation obstructing the venous circulation throughout the body. This regurgitation generally depends on dilatation of the right ventricle consequent upon obstruction to the flow of blood through the lungs, either from chronic bronchitis and emphysema, or mitral obstruction and regurgitation. Dropsy from cardiac disease generally appears first in the feet if the patient has been for some time in an upright position, while dropsy from albuminuria is often first marked by a puffiness of the eyelids. In the former it appears where the greatest obstruction to re-absorption takes place, and in the latter case in those parts where looseness of the cellular tissue most readily allows of exudation.

Local dropsies have, as a rule, local causes. Even the swelling of the foot in anæmic young women, although dependent on a general cause, viz., dilatation of the vessels, and altered composition of the blood, is determined locally by the greater obstruction to the venous circulation which the pressure of the long column of blood in the veins between the feet and the heart presents. In general dropsy also, those parts which are most dependent are apt to become most swollen. It is not, however, always so, as in certain cases the dependent parts have been noticed to be less dropped than the others. This curious phenomenon seems to be due to some vaso-motor nervous influence on the vessels of the dependent part. The local œdema of a brawny character, often noticed around inflamed parts, is partially due to swelling of the tissues themselves, and partially to effusion of fluid between them. This effusion, as has already been mentioned, appears to be caused both by the dilatation of the vessels observed in inflamed parts, and by the greater readiness with which fluids pass through them.

Dropsy in Serous Cavities.—The serous cavities of the body, the arachnoid, pleura, pericardium, peritoneum, &c., are now known to be large lymph-vessels, in communication with the general lymphatic system of the body. The fluid which exudes into them from the blood vessels is, in the peritoneum and pleura, removed, at least in part, by a pumping action in the movements of respiration. The central tendon of the diaphragm contains spaces, the walls of which are alternately drawn apart and pushed together during its ascent and descent. Their separation draws up lymph from the abdominal cavity, and their compression forces it outwards through the lymphatic vessels. The same thing occurs in the costal pleura, during the respiratory expansion and contraction of the chest. The accumulation of fluid in serous cavities may be due, like its accumulation in the cellular tissues, either to diminished absorption or increased exudation. The diminished absorption occurs here in consequence of pressure upon veins, and possibly also

from interference with the pumping action just described. Accumulation of fluid in the ventricles of the brain, or in a sub-arachnoid cavity, is chiefly due to compression of the veins of Galen. In the peritoneum it may be due to obstruction of the portal vein by cirrhosis of the liver or by the pressure of tumours, and it may occur to a greater or less extent in all cavities of the body—from general obstruction of the venous circulation, by disease of the heart or lungs, in the same way as anasarca. It may also occur in these cavities from alteration in the blood, as in Bright's disease. Active dropsy may occur in a serous cavity from inflammation, and here the exudation of fluid is much more rapid than in passive dropsy, the vessels of the inflamed part being dilated and more pervious than usual.

TREATMENT.—The first thing to be considered in the treatment of dropsy is the removal of its cause, if this be at all possible. Where it is due to obstruction of a vein we must hinder, as much as possible, the accumulation of fluid in the vein, by preventing the part from remaining in a dependent position, while at the same time we try to aid the absorption of fluid by the lymphatics by gentle upward friction. Where it is due to obstruction of the circulation in the lungs, we must diminish, as far as possible, all obstructions to the pulmonary circulation by inhalations, emetics, and expectorants, pushed if necessary so far as to cause nausea or even vomiting. Where the obstruction is due to dilatation or valvular disease of the heart, we must aid the organ to contract more powerfully by the use of cardiac stimulants, such as alcohol and digitalis. Digitalis probably has a threefold action in cardiac dropsy, by strengthening the heart, by contracting the vessels, and by stimulating the kidneys. It strengthens at the same time that it slows the cardiac pulsations, and by making the heart contract more powerfully it keeps up the onward current of the blood more efficiently, and at the same time lessens the dilatation which tends to render the valves incompetent. Besides its effect on the heart, digitalis has also an action on the vessels, causing the arterioles to contract, and probably reducing the dropsy in this way. For the contraction of the arterioles produced by digitalis is exactly the converse of the condition which occurs after division of the vaso-motor nerves, and which, as we have seen, produces dropsy whenever any obstruction of the circulation exists. It is not known at present whether digitalis also causes increased absorption, but it seems highly probable that it does so, because we know that it stimulates the vaso-motor centre, and stimulation of this part of the nervous system has been shown by Golz to increase greatly the rapidity of absorption from the lymphatics of the frog. In addition to this action on the heart and vessels generally, digitalis possesses a specific action upon the vessels of the kidney. It is a powerful diuretic, and by thus lessening the amount of water in the blood it will tend to increase the absorption of serous fluid either from the cellular tissue or serous cavities. When digitalis alone does not succeed, the addition of squill and of a small quantity of blue pill frequently increases its efficacy. Digitalis succeeds

best in dropsy caused by valvular disease or dilatation of the heart. It is not so useful in dropsy arising from renal disease, and here other diuretics are preferable. One of the best in spirits of juniper, given either as a mixture or in the form of Holland's gin. Spirits of nitrous ether, nitre, bitartrate of potash, and broom are useful in all forms of dropsy. Copious occasionally succeeds where other diuretics fail. It seems to be most successful in dropsy due to cirrhosis of the liver. Hydrargue catharticus, such as compound jalap powder, elaterium, &c., which cause copious watery secretion from the intestines, supplement the action of diuretics, and by removing water from the body, as well as altering its nutrition, relieve or remove dropsy. In some cases of Bright's disease considerable relief has been obtained by the profuse sweating induced by vapour baths, hot-air baths, jaborandi, or pilocarpin. When the dropsy does not yield to other remedies, the fluid must be removed by paracentesis in the case of serous cavities, and by very small superficial incisions or punctures, or by the insertion of very fine trocars with drainage-tubes attached, in the case of the limbs.

T. LAUDER BRUNTON.

DROWNING, Death by.—Drowning is employed, in an extended sense, to signify death from submersion in a liquid medium, and in a more restricted sense to signify death in consequence of obstruction of respiration so caused. Now, though death must necessarily ensue from asphyxia, when the air-passages are submerged, apart from any other complication, asphyxia is not always the mode of death in those who were alive at the moment of submersion. For death may result from mechanical injuries, concussion, shock, syncope, or apoplexy in the very act, or at the moment, of falling into the water. Devergie estimates that 12.5 per cent of deaths occur from one or other of these causes. In the remaining 87.5 per cent, the phenomena of asphyxia pure and simple are present only in 25 per cent., while in 62.5 per cent. these are more or less modified by the causes above-mentioned, to which must be added the benumbing influence of cold.

When death is not sudden from shock, &c., the ultimate result is the same in the swimmer or non-swimmer: it there be no escape or rescue. All efforts to keep above water fail, vain cluttings are made at whatever comes within reach, water is drawn into the lungs and more or less swallowed, all struggles finally cease, and the body sinks.

The indications of such instinctive efforts form the most important evidence of submersion during life. Drowning is not necessarily to be inferred in the case of a dead body removed from the water, for the body may have been thrown in air or death from other causes—asphyxia among the rest.

THE EVIDENCE OF DEATH FROM DROWNING is cumulative, for we can scarcely say that there is any one indication invariably present which can be looked upon as due to drowning and nothing else. But one or other, or more, of the following appearances are generally found.

External.—The face is either pale, or more or less livid, or frequently blotted if the body has

lain some hours in the water. Foam at the mouth and nostrils is very common; and the tongue is swollen and congested, closely applied to the teeth, or even clenched between them. The skin is pale, or marked here and there by livid discolours, and the muscles of the hair-bulbs are rigidly contracted, causing the appearance of goose-skin or *cutis anserina*. The penis is remarkably retracted, so that it appears quite small in proportion to the size of the individual.

Indications of struggling are frequently seen in excoriations of the hands, mud and sand under the nails, or even weeds, straws, or other small objects, tightly clenched in the hands.

Internal.—The trachea, bronchi, and smaller air-tubes are congested and filled with a mucous froth, more or less tinged with blood. The lungs themselves are congested, edematous, and put on pressure. Pressure on them causes froth to exude into the smaller bronchial tubes and on section a sanguinolent froth and water escape. Indications may be seen of sand, mud, or small weeds drawn deep into the air-passages along with the water in which submersion took place.

The stomach contains water. If this has any special character by which it can be identified with that in which submersion occurred, and not likely to have been drunk to quench thirst, it excludes the theory of its having been swallowed before submersion, and is a strong presumption, if it cannot be said to be a certainty, that it was swallowed during the death-agony, and did not find its way into the stomach after death. The same may be said of water in the lungs.

The right side of the heart and venous system in general frequently present the appearances characteristic of asphyxia, and the brain is often congested.

Without relying on any one sign as conclusive, we may say that a body which exhibits goose-skin, retraction of the penis, excoriations, &c., of the hands, froth at the mouth, water in the lungs and stomach, and congestion of the right heart and venous system, certainly died from drowning. In the presence of some and in the absence of other indications, a careful weighing of all the facts is necessary, but in most cases a satisfactory conclusion can be arrived at.

Complete submersion is usually sufficient to cause death within two minutes, but cases have been recorded of resuscitation after a much longer period. Many of these can be attributed to the exaggerated estimation of time by anxious on-lookers, but there are other well-authenticated instances, which may be explained by the superintention of syncope and temporary cessation of the respiratory process. That which renders resuscitation after submersion less likely than after a corresponding period of mere suffocation is the entry of water into the lungs by aspiration.

TREATMENT.—The treatment of the drowned consists in the persistent use of artificial respiration (see **ARTIFICIAL RESPIRATION**, and **RESUSCITATION**) so long as any signs of life remain, together with the application of means to counteract the great abstraction of body-heat which occurs even when the aërial temperature is comparatively high. Before commencing the movements of artificial respiration, the mouth and nostrils should be freed from water and froth,

by holding the head somewhat low, face downwards, for a few seconds. Artificial respiration should then be immediately proceeded with; and at the same time the wet clothes should be removed and the body wrapped up in warm clothes obtained from bystanders, pending the arrival of warm blankets, hot bottles or bricks, &c., from the nearest habitation. Assiduous friction of the extremities should also be kept up. These directions—artificial respiration excepted—naturally presuppose assistance. If this be not at hand, the operator must rely mainly on artificial respiration. In the performance of artificial respiration by Sylvester's method, especial care must be taken against pressing on the stomach, for as it so frequently contains water, this may be pressed up the œsophagus, and drawn into the lungs by the next inspiratory movement.

When spontaneous respiratory movements commence, attention should be directed to maintain life, by the application of warmth externally, assiduous friction of the limbs upwards, and the administration of a teaspoonful of brandy and water, wine, or coffee. Lung-complications should be watched for and counteracted.

D. FARRIES.

DROWSINESS.—Inclination to sleep. See **SLEEP**, Disorders of.

DRY.—A term applied to certain morbid conditions, to express the entire or comparative absence of fluid exudation or secretion, which is often present in such conditions, for example, Dry Gangrene, Dry Cavity, Dry Catarrh, and Dry Pleurisy. The word is also associated with certain auscultatory signs which convey the impression of want of moisture, for example, Dry Rhonchus and Dry Crackle. See **PHYSICAL EXAMINATION**.

DUCHENNE'S PARALYSIS. See **PSEUDO-HYPERTROPHIC PARALYSIS**.

DUCTUS ARTERIOSUS, Patency of.—See **HEART**, Malformations of.

DUMBNESS.—**DEFINITION.**—The condition of an individual incapable of articulating sounds. Dumbness may arise from a variety of causes, and its prognosis and treatment vary accordingly.

1 **Dumbness due to Deafness.**—The most frequent cause of so-called dumbness is congenital or early acquired complete deafness, or defective power of hearing, so that the patient is unable to acquire in an ordinary way the knowledge of articulate sounds. It is important to bear in mind that complete deafness is not essential to this peculiarity. Dumbness is frequently met with in children and others where the only cause is defective power of hearing.

TREATMENT.—Whether the outcome of complete or partial deafness, the treatment must be based on the belief that the articulating power is latent, and may be developed by imitating the process of speaking in others, and by a methodical training in lip language. It is most important that sign language should not be cultivated at the same time, and that if a language of signs, whether by the hand or gesture, have been previously taught, it should be thoroughly and at once discarded. With patients

who have full intellectual power, and who are trained as indicated above, it will be found that for them dumbness is a misnomer, articulate sounds, although with a defective modulation, being readily acquired. Individuals coming under this category are erroneously called deaf-mutes.

2 Dumbness from Central Lesion of the hypoglossal nerve—This may arise from cerebral hæmorrhage, tumours, or embolism, and the prognosis is most unfavourable. It is usually associated with other paralytic conditions, but is of all the most persistent.

3 Dumbness from peripheral lesion of the hypoglossal nerve—This is much less frequent as a cause of dumbness than central lesions, nevertheless cases are met with where hydratid or other tumours result in dumbness through pressure on the nerve itself.

4 Dumbness from Lead Poisoning—Among the paralyzes arising from the slow effects of imbibition of lead is paralysis of the tongue, with consequent loss of articulating power. This defect is usually associated with grave impairment of other parts.

TREATMENT.—The treatment of dumbness due to lead-poisoning will be best effected by elimination of the poison by the administration of iodide of potassium, and the judicious employment of galvanism to the spinal system.

5. Dumbness from congenital defects of the tongue or of the palate Various congenital local lesions are met with giving rise to dumbness.

TREATMENT—Many of these cases are remediable by surgical or surgical-dental help, followed by methodical teaching.

6 Dumbness from emotional lesions—Dumbness occasionally arises from great emotional disturbance, such as great anger or sudden fright. Moreover, it is often met with, without such marked cause, in individuals, especially of the female sex, having a highly developed emotional life.

TREATMENT—Cases of this kind are usually successfully treated by faradisation about the muscles of the neck, the patient at the same time being encouraged to call his articulating power into action, and in proportion to his success the faradic current being discontinued. The moral treatment here indicated may be greatly assisted by promoting the general health and placing the patient under the best possible circumstances as to hygiene and moral discipline.

7 Dumbness from intellectual disorders—This is by far the most common cause of true dumbness. It may arise from idiosyncrasy or imbecility of a congenital nature, from that which has been acquired early in life, or from dementia as the outcome of acute or chronic brain disease in middle or advanced life. Among the congenitally feeble minded, dumbness is a very frequent phenomenon. This arises from the association therewith of deformed mouths and highly-arched palates; from defective power of co-ordination of the muscles of the tongue, and from an inability to transform ideas into word-signs. In the most profound cases there is such an absence of ideas that language of any kind is not required.

TREATMENT.—The treatment of this kind of dumbness is one which requires great tact, patience, and energy; and this success will be commensurate with these aids.

The physical health of the individual should be carefully attended to, so as to induce, by judicious food, frequent bathing, and warm temperature, the highest amount of nervous energy. The power of co-ordination should be sedulously cultivated by methodical exercises, especially of the hands, leading up to well-derived tongue gymnastics. He should then be taught mono-syllabic sounds, by being shown the object represented by the sound, while he imitates the sound when watching the teacher's lips. Having thus acquired the power of producing the word-sign by imitation purely, he is next taught to repeat it from memory when shown the object only. After nouns have thus been taught, the names of qualities and adverbial expressions should be added, and in this manner articulate speech built up.

Where the feeble mindedness has been acquired after birth, the dumbness resulting therefrom should be treated in a somewhat similar manner to that having a congenital origin, but the prognosis is not so good.

Still more unfavourable is the forecast of dumbness when the result of dementia.

J. LANGDON DOWN.

DUODENUM, Diseases of.—These may be considered under the heads of—1. *Functional disorder*, and 2. *Organic diseases*.

1. *Functional disorder* of the duodenum is said to produce a form of dyspepsia, characterised by pain in the epigastrium and right hypochondrium two or three hours after meals, vomiting, and the distant effects of ordinary dyspepsia—vertigo, headache, drowsiness, burning sensation in the soles of the feet and palms of the hands, &c. Imperfect chymification which attends ordinary dyspepsia may induce these symptoms by generating products which irritate the duodenum. The treatment is mainly that of disordered digestion. The bowels and the diet are to be carefully regulated, and such remedies as alkalies, bismuth, oxide of manganese, prussic acid, or hydrochloric acid, exhibited, according to the special requirements of each case.

2. *Organic diseases.* These are inflammation; ulceration, and new-growths.

a Inflammation.—TYPHUS:—Duodenitis, Fr. *Duodenite*.—Acute inflammation of the duodenum is usually of a mild catarrhal character. It either forms part of an enteritis, or is an extension downwards of a similar affection of the stomach. The ordinary exciting causes are exposure to cold, and irritating ingesta or acid bile. Usually the symptoms of slight gastric catarrh—a loaded tongue, anorexia, nausea, vomiting of tenacious mucus—are followed by jaundice. When the duodenum is invaded there is said to be fullness and tenderness of the right hypochondrium. As a rule, however, new symptoms are not set up unless the bile-ducts become obstructed by mucus from extension of the catarrh into them, when jaundice supervenes without pain. The attack usually lasts a week or a fortnight, and, with suitable hygienic and dietetic

treatment, passes safely off, it is, however, sometimes followed by jaundice unusually prolonged, and, even when the bile-ducts are free, by prostration and wasting out of proportion to the mildness of the disease in itself. While catarrhal duodenitis does not present characteristic symptoms, it is, however, usually suggested by painless jaundice following exposure to cold, catarrh of the stomach, and enteritis.

TREATMENT.—This consists in rest in bed, warmth, liquid diet, counter-irritation by mustard and hot poultices, and evacuating salines.

Chronic inflammation, resulting in thickening of the mucous and submucous tissue, and even adhesion of the duodenum to adjacent organs is usually associated with chronic ulceration, or with cancer of the duodenum, pancreas, liver, or other structures. Contraction of the duodenum produces symptoms of obstruction similar to those arising from stricture of the pylorus.

b. Ulceration.—*Perforating ulcer*, similar to that of the stomach, is said to be more frequent in men than in women, and hardly ever to occur during childhood; while it frequently follows severe and extensive burns and scalds. The ulcer, usually found in the upper horizontal portion, when recent has clean-cut edges free from swelling. The wall of the duodenum may be perforated, either without previous adhesion, being followed by the signs of general peritonitis, or with adhesion to adjacent parts, such as the liver, the gall-bladder, the pancreas, the colon, the hepatic artery, or the posterior wall of the abdomen—into which ulceration extends to a variable extent. Ulceration may induce stricture of the duodenum or obliteration of the bile-duct. As a rule the symptoms greatly resemble those of perforating ulcer of the stomach, more frequently, however, the disease is latent, and induces very obscure dyspeptic symptoms prior to fatal perforation. Jaundice is not more common than in the similar affection of the stomach. In burns and scalds perforation seldom occurs before the tenth day.

The duodenum may be ulcerated by the action of a gall-stone passing into it directly from the gall-bladder.

c. New growths.—The most important of these is scirrhous cancer, which may involve the walls of the duodenum, usually by extension. It tends to produce obstruction, or it may set up chronic duodenitis, or block up the bile-duct, and thus give rise to jaundice.

DURATION OF DISEASE, see DISEASE, Duration of.

DYNAMOMETER (*dynamus*, power; and *metron*, a measure).

DESCRIPTION.—The dynamometer is an instrument originally invented by M. Duchenne, of Boulogne, for measuring and accurately recording the strength of the hand-grasp, and also for measuring the traction power capable of being exerted by other groups of muscles. The result is shown by an index, which traverses a semi-circular dial bearing a scale graduated so as to

enable the observer to record the number of kilogrammes which the applied pressure or traction represents. In practice this instrument has been principally employed for estimating the absolute or comparative force of the hand-grasp; and in view of this restriction, Duchenne's instrument is needlessly complex. It has, moreover, the absolute disadvantage of being a little too broad, and requiring too much strength in the part of the patient to move the index over the lower figures of the dial. A patient with a small amount of motor power, especially if the hand is small, is often unable to set the index of this dynamometer in motion. A cheaper, simpler, and narrower instrument has, therefore, been devised by English makers, the index of which can be moved by the application of a much smaller amount of power. This consists of a simple elliptical ring of steel, to the inner and anterior face of which is attached a brass semi-circular dial graduated with two rows of figures representing pounds instead of kilogrammes. The compression of the steel ring, by lessening its shorter diameter moves a metal bar projecting from and sliding in a groove behind the dial, and thus by rack-work communicates its movement to the index.

Uses.—The dynamometer is a useful instrument, inasmuch as it enables us accurately to ascertain the relative compressing powers of the two hands in cases of incipient or actually developed hemiplegia, and also to learn in a positive and definite manner, from time to time, the amount of improvement or the reverse which may have taken place. Since the power of the muscles of the fore-arm and hand, like that of other groups of muscles, varies a good deal with the general state of health of the patient, the dynamometer is also capable of yielding valuable information concerning the strength of the patient, even where we have not to do with a case of paralysis. Any instrument which, in the place of fleeting and more or less vague impressions made upon the mind of the practitioner at the time, enables him to make a more accurate record in figures in his note-book, is a clear gain to practical medicine—more especially when its use involves no appreciable loss of time.

H. CHARLTON BASTIAN.

DYSAESTHESIA (*δύς*, with difficulty, and *αἰσθάνομαι*, I feel).—A term applied to impairment of any of the senses, but especially to that of touch. See **SENSATION, Disorders of**

DYSCRASIA (*δύς*, difficult or bad, and *κράσις*, a mixture). A morbid condition of blood.

This term signifies more than a disposition to disease; it implies the presence of some general disease exerting its pernicious effects upon the blood. Emetic fever, septicæmia, and metastatic inflammations are diseased conditions referable to dyscrasie. A person sickening for a fever is the subject of a specific dyscrasia. See **BLOOD-DISEASE**.
R. DOUGLAS POWELL.

DYSENTERY (*δύς*, with difficulty, and *έντερον*, an intestine). **SYNON:** Fr. *Dysenterie*; Ger. *Dysenterie*.

DEFINITION.—A specific febrile disease, charac-

terized by considerable nervous prostration and inflammation of the solitary and tubular glands of the large intestine; sometimes ending in resolution, but frequently terminating in ulceration, occasionally in more or less sloughing or gangrene, always accompanied by tormina and tenesmus, the latter being most marked when the disease is located in the rectum or lower end of the sigmoid flexure; stools at first more or less feculent, later on yielding dysenteric products without much if any feculence, such as blood, mucus, slime, and glutinous exudation, or—as in the sloughing or gangrenous forms—like the washings of meat, and possessing a putrid or gangrenous odour, and so-called epithelial, ash-coloured, black, gangrenous, pus-infiltrated or tubular sloughs, chiefly consisting of tough, imperfectly organised exudation.

Ætiology.—In almost all if not in all, situations where malarious fevers abound, as in the vicinity of the swamps and sluggish rivers of tropical and sub-tropical countries, dysentery prevails in proportion to the intensity and frequency of these fevers. When, on the other hand, intermittents and remittents have been extinguished by improved drainage and the conversion of marsh into cultivated land, it becomes equally unknown. In or near the tropics, Great Britain, Canada, the United States, and in many other parts of the world, its diminution has proceeded *pari passu* with the decrement of malarious fevers. There would therefore, seem to be some intimate connexion between the causation of dysentery and intermittent and remittent fevers.

Proximal fevers interfere materially with the nutrition and functions of the digestive organs, and with the proper nourishment and constitution of the blood. Violent congestion of the abdominal visera is one of the special conditions of the different forms of ague. Both the liver and spleen are liable to temporary and repeated engorgement, and so in fact are all the organs which minister to gastric and intestinal digestion. Even where malarious poisoning may never have resulted in any of the various forms of periodic fever, it may impair the power of the organic nerve-centres and the muscular tone of the blood-vessels, thus disturbing the balance of the portal circulation, and leading to more or less permanent repletion or congestion. As the congestion is most embarrassing during digestion, interfering with the appetite, and the capacity for digesting and assimilating food, its repeated and prolonged existence must deteriorate the quality and modify the quantity of such important secretions as the gastric juice, the bile, the pancreatic juices, and those furnished by the follicles of Lieberkuhn, and by Branner's and the solitary glands. Crude alimentary principles are thus assimilated from the intestinal tract. The liver is especially liable to functional derangement from the stagnation and slowing of the portal circulation and thus it happens that, in dysentery hepatic impairment is almost an invariable accompaniment. Each being some of the abnormal conditions produced by the operation of malaria in its active or latent form upon the chylipoætic viscera, it is not surprising that, under the prolonged strain, certain portions of the alimentary mucous membrane

should break down. Why the solitary glands of the large intestine should be the special seat of dysentery, whilst the corresponding glands in the small intestine should, with few exceptions, escape, it is, in the present state of our knowledge, impossible to say. The most that can be hazarded is, that the elementary structures of these glands take on morbid action through the operation upon them of a *materies morbi* derived directly from their blood-supply. That this poison exists in the blood may be inferred from the fact that constitutional disturbances invariably precede and accompanies the earlier stages of acute dysentery.

Unwholesome drinking-water is a fertile proximate and exciting cause of dysenteric disease. Bad and unwholesome food of whatever description, by providing aliment incapable of being perfectly digested, may act in producing the disease. In like manner impure air may, by preventing the proper aëration and depuration of the blood, and by promoting the retention in it of massimizable material, light up dysenteric inflammation of the solitary glands. The transit of acrid and vitiated bile and other secretions poured into the digestive canal often operates as an exciting cause, and frequently determines a morbid action which might be otherwise righted by resolution, to advance to ulceration, sloughing, or gangrene. It is thus that many a simple but neglected case, scarcely at first distinguishable from diarrhoea—unless indeed every evacuation is most carefully washed and scrutinised—ends in destruction of large masses of the mucous membrane, and death, from the conjoint effect of exhaustion and shock from the separation of the sloughs. Indigestible articles of diet, which cannot be reduced by the juices of the digestive tract to a condition admitting of ready absorption, may act as local irritants and exciting causes. Not only is this so in the earliest visible stage or that of active congestion, but it becomes much more susceptible of demonstration in the exulcerative and ulcerative phases of the disease, by the repeated investigation of the subjective and objective indications. Thus the aggravation of the tormina and tenesmus in adults and children is traceable to indiscretion in diet, or to the passage of undigested morsels of food, recognisable in the stools. Sudden vicissitudes of temperature from a high to a low range, or exposure to damp and cold combined, especially when the vital powers are physiologically depressed, by checking the excretory action of the skin and diminishing the cutaneous circulation, augment the portal congestion and excite dysenteric disease. This is probably the reason why, in a large proportion of cases, the onset of the disease is ushered in towards midnight or the early morning. The influence of epidemic states of the atmosphere in the causation of dysentery, signifies only that it is most prevalent at those seasons when malarious fevers are most abundant. As there is an intimate connexion between the existence of malaria and the prevalence of dysentery, it is not difficult to understand why, both as regards type and seasonal frequency, dysentery should bear a striking relation to the severity and seasonal prevalence of malarious fevers.

Is dysentery a contagious or communicable

Disease 1.—Whilst many of the older physicians held that it might be spread by contagion from person to person, it may be affirmed that the experience of most modern practitioners is altogether opposed to this view. There is no clear and unimpeachable evidence to demonstrate that it is propagated in the same way as typhus or smallpox. It may possibly be communicable, like typhoid fever, through air, water or food—liquid or solid—charged with material derived from the undisinfected and putrefying products of the disorder. Be this, however, as it may, the complete disinfection or destruction of the alvine excretions should always be regarded as a sanitary measure of supreme importance.

ANATOMICAL CHARACTERISTICS AND PATHOLOGY.—The dysenteric process generally consists of a specific inflammation of the solitary glands (Parker, Baly, and others). The *first* visible change is congestion, the vessels surrounding and penetrating the capsules being turgid and engorged with blood. The *second* change is augmentation of their contents from the accumulation of albuminous exudation, and enlargement 'from the size of a millet seed to a small shot' (Baly). The *third* change is, provided the inflammation advances, rupture of some of the capillaries in the interior of these little vascular glands, extravasation of blood, with the area of the ordinary dark point on the free aspect increased. The *fourth* stage is now marked by atrophy and molecular disintegration of the free aspect of the capsular wall, and escape of its morbid gelatinoid blood-tinged contents into the canal of the intestine. This is the rule, but, in very exceptional cases, the capsule may burst through the attached portion, lighting up inflammation in the neighbouring connective tissue and muscular coat. In a large number of instances, the morbid process may stop short, under proper treatment, at any of the first three stages, and repair is then effected by resolution. In many cases the morbid action is cut short after the completion of the fourth stage, without further extension of the disease. The adjoining follicles of Lieberkühn do not, in these cases, necessarily participate, to any great extent, in the diseased process. Under these conditions, when the whole of the exudation has been expelled, the glands regain their tone and functions, and recovery—rapid and complete—ensues. It is not often possible to illustrate these conditions in the post-mortem room, because when death supervenes from dysentery alone the ravages committed upon every structure of the mucous membrane are so extensive as to destroy the earlier physical phases of the disease. In some cases, however, which have died from intercurrent affections, the writer has been able to demonstrate the earliest stages successfully to his students, at a period prior to the implication of Lieberkühn's follicles, of which the mucous membrane is in great part composed, and to exhibit to them the gelatinoid exudation, termed by others 'gelatinous mucus,' free from or tinged with blood taken from enlarged and diseased solitary glands (*Indian Annals of Medical Science*, p. 190, No. xxiii, 1868).

When, owing to neglect, to constitutional defect in spite of the most careful therapeutic and hygienic management, or to intemperance or quantity

of the specific poison, the disease is not cured by resolution, the disintegrating or ulcerative process is developed. The whole of the solitary glands engaged periton. The ulceration involves the neighbouring tubular glands, leading to ulcers varying from the size of a millet seed to that of a florin or more in depth generally extending to the submucous connective tissue, and not infrequently laying bare the circular lamina of the muscular coat, sometimes involving the longitudinal layer and perforating it as well as the peritoneal coat, thus admitting of the extravasation of the contents of the bowel into the peritoneal cavity and lighting up peritonitis, which, if general, is invariably mortal but which, if local and confined to the close vicinity of the perforating ulcer is not necessarily so.

The ulcers vary in appearance, size, and shape. They may be mere abrasions without much loss of structure, *minute* though penetrating rather deeply into the submucous connective tissue; *irregular*, *serpentine*, or *rodent*, with here and there portions of the surrounding mucous membrane undermined and pitulous, *transverse*, embracing partially, or completely, the entire circular outline of the mucous membrane, *circular* or *oval* with regular and even margins, or *tubercular*, involving the whole substance of the mucous membrane, looking as if they had been punched out of it. These ulcers, as generally observed in the post-mortem room, are free from sloughs, and present a pale ashy appearance. Sometimes they are of a vermilion or purple colour, from active or passive congestion. They are often covered with flakes of tenacious lymph or exudation, and thus may sometimes be seen spread over the neighbouring mucous membrane. The floors of these ulcers are usually formed by inflamed and thickened submucous areolar tissue, but sometimes this has all been destroyed, and then they are constituted of the muscular coat, thickened and infiltrated by inflammatory products, and when the muscular structure has itself yielded to the ulcerative process, they are made up of congested and swollen peritoneum which, as already stated, occasionally becomes perforated.

When the ulceration proceeds solely by molecular disintegration massive sloughs are not observed. But when, as not uncommonly happens in asthenic, malarial-stricken, tubercular and worn-out constitutions, tissue-death occurs *en masse*, at an early period of the attack, sloughing of the mucous membrane, together with portions of the muscular coats, or gangrene, is to be seen. These sloughs, or gangrenous portions of tissue, may be limited in extent. Some or all of them may be successfully detached during life, and can be identified as they are examined from time to time in the stools. In the post-mortem room they may be found partly detached and lying loose, mixed with the fluid contents of the bowel, or attached more or less firmly, sometimes compact, nodular, ecchymosed, gray or olive coloured, green or yellow and pus-infiltrated, black, flaky, shredly, shaggy, flocculent like pieces of teased cotton-wool, or ragged and stringy. In the truly gangrenous dysentery, the mucous and muscular coats are enormously thickened and large portions are found gangre-

nous, varying in colour from a pale olive to purple or black. These appearances and conditions may be restricted to the cæcum and ascending colon, or to the sigmoid flexure, but sometimes they are co-extensive with the internal structure of the large intestine from the ileo-colic valve to the anus. When the ileo-colic valve becomes destroyed, invagination of the lower end of the ileum into the cæcum sometimes happens, causing intestinal obstruction. Occasionally many inches of the gangrenous mucous membrane, with or without the muscular coat, is either found hanging loose in the lower part of the gut, or in process of being detruled from the anus.

In ordinary acute dysentery, advancing to ulceration or sloughing, repair is, doubtless, accomplished, as a general rule, by granulation and cicatrization. This process can be readily observed in dysenteric lesions of the mucous membrane of the lower end of the rectum, and in healing of the surgical ulcer within the verge of the anus. The reason why repair is frequently accomplished so slowly is because, owing to the irritation caused by the excited vermicular contraction of the gut and the passage of flatus feces, and other products, it is impossible to command the physiological rest necessary for speedy and substantial granulation and cicatrization. Unless the destruction of tissue is very great, the contraction due to cicatrization does not occasion much turn of inconvenience. But if it embraces a large portion of or the whole circumference of the mucous membrane, the subsequent contraction may produce dangerous narrowing of the calibre of the gut, or structure of the sigmoid or rectum. The thickening and contraction, especially in the attenuated victims of chronic dysentery, can be identified by physical examination. These constrictions are frequently the mechanical cause of constipation and fecal accumulations.

There is no valid reason for believing that, in true dysenteric ulceration, the lost tissue is ever actually reproduced. When the ulcers have been small, the contraction following repair is sufficient to bring the follicles of Lieberkuhn on all sides into close juxtaposition. And thus it is which has given rise to the impression among some pathologists, that the lost tissues have been renewed by a process of development and growth. But whenever the ulcers have been too large to admit of obliteration, microscopical examination shows that they have been bridged over by cicatricial tissue, devoid of solitary and tubular glands and sparingly supplied with blood-vessels and absorbents.

In addition to the above anatomical characters, the mesenteric glands are generally found to be enlarged, and as an accompaniment or sequel, organic disease of the liver or spleen is not infrequently discovered to complicate the disease.

SYMPTOMS.—Every attack of acute dysentery is preceded by disordered digestion and constitutional disturbance, indicated by loss or capriciousness of appetite and furred tongue, constipation alone or alternated with looseness, dryness of skin, occasional chilliness and general malaise, with slight rise of the evening temperature. These signs may be viewed as cotemporaneous with the progress of the morbid action going on in the soli-

tary glands. As the disease advances, there is more marked chilliness, succeeded by distinct feverishness. If the bowels have been confined, they now act spontaneously—expelling, at one or more acts of defecation, almost the whole of the contents of the large intestine. If they have been loose, with or without aperient medicines, the feculence is not so great in quantity. But in either case, beyond a little mucus, there is not as yet any discoverable dysenteric product in the stools. Prior to this conservative evacuation of the bowels, the febrile excitement sometimes runs high, there is thirst, bad taste in the mouth, flatulency, a variable amount of nervous and muscular debility, griping, an accelerated and irritable pulse, restlessness, disturbed sleep, or actual insomnia. During, and immediately after, each evacuation there is tenesmus or painful straining—most intense in those cases where the disease is located in the descending colon, sigmoid flexure and rectum. The stools are offensive but there is nothing at this stage pathognomonic in their colour. If, as frequently happens in private practice, the patient comes under treatment at this period, a small dose of castor oil guided by laudanum, or a full dose of ipecacuanha, with absolute rest in bed and bland liquid nourishment, is sufficient, in a certain proportion of cases, to put a stop to the morbid action, and to promote cure by resolution in from twenty-four to forty-eight hours.

When however, the disease persists, the symptoms continue in an aggravated form. The tormina and tenesmus become intensified; the desire to go to stool is more frequent, and to remain on the stool or bed-pan more irritable and enduring, especially if the disease be concentrated in the sigmoid flexure or rectum. In rectal dysentery, there is dysuria, frequent micturition, and sometimes retention, from spasm due to reflex action, necessitating catheterism. The consumption of solid food—even of the most digestible kind—provokes and aggravates the tormina. The griping and tenesmus are now so intensified in degree, and increased in frequency, that such recurrence of them produces much depression and exhaustion, and a pinched and anxious expression of the countenance, with augmented frequency and weakness of the pulse. There is abdominal tenderness. During the acute of the tormina, the patient experiences difficulty in localising this tenderness. He will then declare that he feels agonising pain over the greater part of the abdomen, with or without the application of pressure. But in the absence of the tormina, careful palpation will enable the practitioner to localise it in those portions of the intestine above the rectum affected by dysenteric inflammation. At this stage the tumefaction of the walls of the gut is seldom great enough to be distinguished through the abdominal parietes. The scanty stools are now characteristic, consisting of much exudation tinged with blood, or bloody mucus or slime from the inflamed tubular glands, with isolated portions of gelatinoid exudation, more or less coloured with blood from inflamed and ruptured solitary glands, and with little or no feculence. These conditions are cotemporaneous with the rupture of the affected solitary glands, and a highly inflamed state of

the adjacent follicles of Lieberkühn, as well as of the subjacent and intervening connective tissue. The muscular tissue, though not yet necessarily inflamed, is nevertheless hyperæsthetic. It is this hyperæsthesia which has more to do with the production of the agonising tormina than the diseased glandular organs implanted in and forming a constituent portion of the mucous membrane. These are the symptoms presented in a goodly number of cases met with in private practice, and in a smaller proportion admitted into hospital. The disease is said to have lasted from two to six or eight days. In uncomplicated cases occurring in tolerably good constitutions, they generally yield, without extension of the mischief, to rest, bland liquid food, and full doses of opæmuanha.

In cases which have been neglected or aggravated by indiscretions in diet and drink, or by diathetic or other defect of constitution, the dysenteric process passes on to ulceration. If the patient has not been brought under proper therapeutic and hygienic management, the tormina, tenesmus, local tenderness, and hardening of the superimposed abdominal muscles are augmented. The calls to stool are more frequent and painful. The urine is scanty and high-coloured, and is sarcharged with lithates and bilinary pigment. The stools mainly consist of the foreign products already described, but in greater quantity, are now possessed of a peculiar sickly smell, and yield portions of exudation in masses of greater or smaller size, simulating sloughs, but which, on microscopical examination, are seldom found to afford positive evidence of dead tissue-elements.

Unless the disease bends to treatment, it may terminate in sloughing. This may be restricted or extensive. Death of portions of the mucous membrane is always accompanied by vital depression or well-defined muscular and nervous prostration, cardiac enervation, and an accelerated and feeble pulse. In some cases, tissue-death *en masse* happens at an earlier period, even before the rupture of the solitary glands, and the sloughs can be discovered in the stools in from the eighth to the thirteenth day. The acme of vital prostration is manifested during the detachment of the sloughs, when the exhaustion is often much increased by hæmorrhage. Improvement in the strength, volume, and slowing of the pulse, and in the expression of the countenance, the comparative relief from tormina and tenesmus, clearing of the tongue, and the substitution of feculence for dysenteric products in the stools, signify, in these cases, the probable cessation or turning-point of the disease. The converse implies that the sloughing is extending, and a succession of sloughs of various kinds, with or without muscular structure, continues to be passed, which, in the process of separation, are accompanied by much bleeding, especially in patients poisoned by malaria or afflicted with the scorbutic or hæmorrhagic diathesis. The abdominal tenderness and hardening of the parietal muscles are marked during the separation of the sloughs. The affected portions of the colon can be felt to be swollen, doughy, and 'puddingy' (Chovvers). The skin, in unfavourable cases, becomes clammy, features and eyes shrunken, body emaciated, appetite in abeyance, thirst great and distressing.

tongue dry and brown, pulse feeble and running, and stools extremely offensive, bloody, slimy or watery, with varieties of sloughs and exudation. The sensibility becomes so blunted that the stools are passed without much pain—often involuntarily, and the patient eventually dies from sheer exhaustion from the extension of the sloughing, or the end may be accelerated by perforation of the bowel in one or more places, leading to extravasation of some of the contents of the intestine into the peritoneum, and general peritonitis.

Sometimes, from the commencement of an attack, or during the course of acute dysentery, rapid sloughing, passing into gangrene, of large patches of mucous membrane, attended by increasing prostration and soon merging into collapse, forms the chief pathological condition. As this extends until, in many instances, it involves almost the whole of the mucous membrane, submucous tissue, and muscular structure, it is characterised by intensified collapse. The tormina and tenesmus at first exerting, suddenly disappear to the delusive relief of the sufferer. Until the gangrene has spread to a great extent, the stools contain a large quantity of slime, blood, pellicular-looking exudation, and much gelatinous exudation, but as the living mucous membrane becomes diminished, these products also decrease, and, in their room, we notice a watery product of a dark purple or black colour, resembling the washings of meat, giving off an incomparably offensive and gangrenous odour. To the naked eye, and on washing, these stools seem to be absolutely devoid of feculence. They yield a granular sediment of a black colour—gangrenous *débris* blackened by the combination of sulphur with the iron of disorganised cruorin. The abdomen, at first doughy, becomes tympanitic and free from pain on pressure and the surface cold and clammy; the countenance resembles the haggard and surken appearance presented during the alid stage of cholera, the tongue is dry brown, and fissured, the pulse is thready and rapid; food and medicines are rejected, the dejects are passed involuntarily, perception is blunted, delirium supervenes, and the patient at last succumbs, worn out and exhausted, in from the sixth to the thirteenth day, according to the range and severity of the disease and the constitutional power of the patient.

Chronic Dysentery.—This is sometimes the result of acute dysentery, in spite of the most appropriate management, in persons poisoned by malaria and weakened by fatty or waxy degeneration of the spleen or liver, or both, and in strumous or scurvy constitutions. The dysentery may be so pronounced that the material exuded is incapable of healing up the ulcers by granulation and cicatrization. The ulcers are repeatedly disturbed by peristalsis, the passage of flatus, fæces, undigested morsels of solid food and the acid unithed secretions of the liver, stomach, and pancreas. Thus they are liable to become irritable from renewed congestion and inflammation. The muscular coat participates in the excitement and becomes infiltrated with exudation, which eventually becomes organised and leads to thickening. The floors and sides

or the ulcers are constituted of unhealthy structure. The difficulty thus experienced in effecting repair is augmented. In other cases the intestine becomes atrophied, attenuated, and transparent. The stools are made up of serous exudation, slime, blood, and sometimes of puriform material, with feculence generally unformed. Almost every stool will be found on washing to contain dysenteric products. The appetite is uncertain; the tongue often clean, shining, and devoid of epithelium, the pulse weak and irritable, and the abdominal tenderness easily localised. Thickening can often be detected. Tormina are always present, and unless the disease be confined to the cæcum or ascending and transverse colon, there is tenesmus. Multiple abscesses of the liver frequently supervene and carry off the patient, or after months or years of suffering he may perish from inanition and exhaustion, or from intercurrent disease.

Complications.—Acute dysentery is frequently complicated by the various forms of malarious fever, typhoid fever, the tubercular or the hemorrhagic diathesis, purpura, scurvy, hepatic and splenic enlargement, malarious cachexia or abscess of the liver, and in children by dentition. In every case of dysentery the strictest attention should be paid to existing complications. In patients inhabiting malarial districts, and those following a seafaring life, the gums should be carefully scrutinised and the cutaneous surface examined with a view to ascertain the freedom or otherwise from purpura or scorbutic taint. The history of the patient should be gone into, in order to make out the probable diathetic proclivities—acquired or hereditary.

SEQUELÆ.—That abscess of the liver, single or multiple, frequently follows acute and chronic dysentery, is indisputable; but whether as a result of the general condition existing, or of local pyæmia poisoning or embolism originating in the veins within the area of the ulcers, is still an open question. Dysentery sometimes terminates in permanent thickening of the parietes of the gut with eventual contraction or stricture, causing constipation, fecal accumulation or obstruction. When the seat of stricture can be reached, as in the lower part of the rectum, much relief can be afforded by simple incision and subsequent dilatation by means of bougies. Fissure of the anus, or ulcer within the verge of the anus, is a common sequel. Once diagnosed by examination of the stools and by means of the speculum, it admits of speedy relief by incision and after surgical management.

DIAGNOSIS.—From diarrhoea, dysentery can be diagnosed by the abdominal tenderness, tormina, tenesmus, and the existence of dysenteric products in the stools. Dr. Edward Gooden, late Professor of Medicine in the Calcutta Medical College, was the first to carry out the practice of washing the stools in dysentery and diarrhoea. The stools are first examined as they lay in the stool-pan. Water is then added in considerable quantity. After a short interval, to allow the dysenteric products to sink to the bottom, the superatant fluid is gradually poured off. The washing is repeated until the foreign products remain clean and destitute of much smell. When these products are putrescent, or perhaps in all cases,

it is convenient to wash the stools with a solution of carbolic acid or other colourless disinfectant. Dysentery is diagnosed from *fævus* or *ulcer of the rectum* by the fluid or loose character of the stools, with dysenteric products, and by the absence of ulcer, as determined by examination by means of the anal speculum.

PROGNOSIS.—*Favourable*.—The following are to be regarded as favourable features in the prognosis of any given case:—The ordinary uncomplicated form of acute dysentery; early subsidence of the constitutional disturbance; a steady, firm and strong pulse, with diminishing frequency and increasing power; moderate abdominal tenderness, absence of tympanites; a placid and normal expression of countenance; absence of sloughs or putrescent matters in the stools; early subsidence of tormina and tenesmus with the appearance of feculence and the contemporaneous decrease of dysenteric products; return of appetite and power of digesting and assimilating food, and the absence of inflammatory or suppurative mischief in the liver.

Unfavourable.—Unfavourable features, on the contrary, are—The persistence of an elevated temperature, quick pulse with increasing feebleness, sudden freedom from tormina, tenesmus, and abdominal tenderness, with great vital depression or collapse, doughy thickening of the colon with dullness on percussion where there should be resonance, sudden increase of abdominal tenderness, with hiccup, nausea, vomiting, and great nervous prostration, tympanites, and peritonitic pain with constant hardness and tension of the abdominal muscles, increase of putrescent and gangrenous products in the stools like the washings of decomposing flesh; excessive hemorrhage from the bowel, bleeding from chapped and fissured lips, gums, and mouth; harsh, dry, black or glazed tongue, delirium; picking at the bed-clothes, scantiness or suppression of urine.

TREATMENT.—Should an aperient be required in the congestive, exudative, or ulcerative stages of acute dysentery, or in sudden relapses supervening upon chronic forms of the disease, the readiest, simplest, and most painless is a tepid water enema of from two to four pints. After the operation of the enema, or immediately the patient presents himself suffering from any of these dysenteric conditions, in those cases where no preliminary aperient is indicated, a turpentine epithem or mustard plaster should be applied to the epigastrium for twenty minutes. At the same time from twenty grains to a drachm of *opercuana* suspended in two drachms of syrup of orange-peel and four drachms of water, or in half an ounce of infusion of camomile, with ten grains of carbonate of soda or bicarbonate, or simply made up into conveniently sized pills, should be administered. The recumbent posture, with the head lower than usual, should be enforced. Liquids should be resisted as much as possible for an hour or two. Thirst may be quenched by sucking pieces of ice, or, when this cannot be procured, by cold water in teaspoonful at a time. Nausea will probably occur; perhaps, in some cases, retching and vomiting. But as the vomiting is exceptional, and when it does occur seldom happens before the lapse of an hour after the

exhibition of the drug, the ejected matter usually consists of small quantities of gastric secretion. Should the ipecacuanha be rejected, the dose should be repeated as soon as the stomach has been tranquillised. It will be found beneficial to time the large doses, so as to allow of one being given night and morning so long as their use is considered necessary. The signal for the relinquishment of these doses is freedom from tormina and tenesmus, with the occurrence of refreshing sleep, feculent, bilious, or ipecacuanha stools, and restoration of the primary processes of assimilation. If no great amount of disorganisation of the mucous membrane has taken place, these favourable changes are frequently noticed after the administration of the first or second dose, and even if undoubted ulceration has set in, they are generally discerned on the second or third day or earlier. In either case the drug should be abandoned, as the disappearance of the tormina and tenesmus and the absence of mucus, blood, and slime from the stools indicate the cessation of dysenteric inflammation, and that the affected portions of the bowel have been placed in the most favourable condition to undergo cure by 'resolution,' if the case has not proceeded to ulceration, or by 'granulation and cicatrization,' if ulceration or even sloughing has already taken place. Chalk-mixture with hyoscyamus and astringents is now quite sufficient to wind up the cure. In some cases ferruginous and bitter tonics are demanded, to give tone to the digestive organs, and to improve the condition of the blood. Counter-irritation by means of turpentine epithems and mustard plasters to the abdomen, or fomentation, are valuable adjuncts in the management of the disease.

The diet should consist of chicken broth, beef-tea, essences of chicken, mutton, or beef, sago, arrowroot, or tapioca; and small quantities of port wine or brandy. During the active period of the disease all food should be given in a liquid form. The disturbing effect of the ipecacuanha given as above directed is only temporary. Abundance of time is, therefore, available between the large doses for the digestion and assimilation of liquid food. As the stools become more feculent and consistent, solid food in the shape of tender chicken, lamb, and mutton, with biscuit and bread, light sago rice, or tapioca pudding should be allowed. Potatoes and other vegetables should be avoided until the tone of the digestive system has been fully re-established. When the dysentery is complicated with a purpuric or scorbutic condition of the blood, the administration of the juice of the grape, orange, pomegranate, lime, and leaf sorbet are essentially necessary as dietetic rather than therapeutic agents.

Opium by the mouth is seldom required. When swallowed it 'locks up' the secretions of the liver, pancreas, and alimentary mucous membrane, rather favouring than reducing the inflammation of the solitary and tubular glands. These bad effects counterbalance the benefits derived from the sleep, diminution of peristaltic action, and temporary decrease of tormina and tenesmus consequent on narcotism. This explains why the real character of the disease is often completely masked by opium, and why

apparent amendment is taking place, whilst destructive ulceration and sloughing of the mucous membrane is rapidly extending. As ipecacuanha speedily brings about all the good without any of the evil effects of opium, this narcotic, in any form, excepting as an emetic or suppository to relieve tenesmus, particularly in sigmoidal or rectal dysentery, is not only superfluous but injurious. There is less objection to uniting the ipecacuanha with such remedies as are acknowledged to possess the power of lessening the irritability of the stomach, and of increasing its tolerance of the drug, without interfering with the functional activity of those organs whose secretions we are endeavouring to promote with a view to rectify the disturbed balance of the portal circulation. On the contrary medicines of this order may be beneficially associated with ipecacuanha—such as carbonate of soda, bismuth, chloroform, camphor, and hyoscyamus.

When dysentery occurs in pregnant women, large doses of ipecacuanha are not contra-indicated, because, if the disease be allowed to proceed (which is more likely to happen under the old than the ipecacuanha treatment) abortion or premature labour is almost certain to follow, and when such a complication supervenes, in the later months of gestation, the mortality almost surpasses that of any other disease. When the dysenteric inflammation is summarily put a stop to by the ipecacuanha, abortion or premature labour is prevented. Under the opiate method of management, premature labour is not averted, but, in the majority of cases, occurs at the acmé of the disease, when the sloughs are being thrown off, and the patient succumbs to the conjoint shock to the system. In dysentery complicated with pregnancy opiate enemata to relieve irritation in the rectum are more essential and permissible than under other circumstances.

In the acute dysentery of children ipecacuanha is invaluable. For a child of six months a grain, and for a child of one year two grains, should be given with an equal quantity of carbonate of soda, night and morning until the tormina, tenesmus, and slimy and bloody stools are replaced by relief from pain and by feculent evacuations. It will not often be necessary to continue the drug beyond two or three days at a time. But it should be recollected that the disease adheres with greater tenacity to children than to adults; and although we observe that ipecacuanha has an immediately beneficial effect in diminishing the blood, mucus, slime and frequent stools, still we find that dysenteric or shirry motions with undigested food continue to pass. In that case the ipecacuanha, combined with chalk, bismuth, carbonate of soda, or aromatic powder, should be repeated, once or twice a day, for a certain period, till healthy evacuations are restored. The gums must be lanced when necessary; turpentine liniment or stupes may be applied to the abdomen, weak chicken-broth or arrowroot should be temporarily substituted for milk, and, above all, food must be given in small quantities at a time, and at regularly stated periods. From the age of one year the dose is regulated by adding one grain for each additional year of age up to eighteen, when the doses indicated for adults should be employed.

In cases where evident malarious taint pervades the system and complicates acute dysentery, disulphate of quinine is indispensably necessary. A scruple of the antiperiodic will be most speedily absorbed if dissolved in water acidulated with sulphuric acid, and the exhibition of this may precede by an hour the first dose of ipecacuanha. Ten-grain doses should be given midway between the large doses of ipecacuanha, or during abatement of febrile excitement, until the feverish symptoms have been subdued. Quinine here is quite as important as ipecacuanha, for, until it has successfully checked the disturbing influence which malarious poisoning exercises upon the capillaries of the portal and general circulatory systems, the good effects which ipecacuanha produces are only temporary and incomplete. The mildest febrile exacerbations of a miasmatic origin re-excite dysenteric action, and thus undo the good effected by the action of the ipecacuanha. Hence, the urgent necessity for removing without delay every vestige of malarial or active malarious fever complicating dysentery. No drug enables us to accomplish this object so safely and so quickly as the disulphate of quinine in large doses.

When ipecacuanha fails to preserve the life of the patient its failure may be generally attributed to—(1) coexistence of abscess of the liver; (2) unchecked malarious poisoning, (3) permanent enlargement of spleen or liver, or both, (4) irretrievable constitutional cachexia, (5) Addison's disease of the supra-renal capsules, (6) morbus Brightii, (7) phthisis or tuberculosis, (8) strumous disease of the mesenteric glands, (9) peritonitis with or without perforation of the gut, or (10) the existence of extensive sloughing or gangrene.

The advantages of the 'Ipecacuanha Treatment' (for the revival of which the profession are indebted to Mr Scott Docker, of the 2nd battalion of the 7th Royal Fusiliers stationed at the Mauritius.—*Lancet* of July 31 and August 14, 1858) in the congestive, exudative, and ulcerative stage of almost every form and type of acute dysentery, as well as in the acute attacks supervening upon chronic dysentery, may be briefly stated to consist in (1) its simplicity, (2) its safety, (3) its certainty compared with any other method, (4) the promptitude with which the inflammation is stopped, (5) the rapidity with which repair takes place—(a) by resolution or (b) by granulation and cicatrization, (6) conservation of the constitutional powers, (7) abbreviation of the period required for convalescence, (8) decrease in the frequency of chronic dysentery, (9) decrease in the frequency of abscess of the liver, (10) diminution of mortality to cases treated—all of which are accomplished, (a) without local or general blood-letting, (b) without sedation, (c) without emolument and irritating purgatives, and (d) without ejection by the mouth.

Ipecacuanha in large doses may be said to fulfil many important indications. It produces (1) all the benefits that have been ascribed to blood-letting without robbing the system of one drop of blood, (2) all the advantages of mercurial and other purgatives without their irritating action, (3) all the good results of antimonials

and sudorifics without any of their uncertainty, (4) all the euthanasia ascribed to opium without masking, if not aggravating, the disease whilst the mischief is silently accumulating within. Thus, we possess in ipecacuanha a *non-spoliative antiphlogistic, a certain cholagogue and emetic-purgative, a powerful sudorific, and a harmless sedative to the heart and the muscular fibres of the intestines.*

The objections which have been urged against large doses of ipecacuanha in dysentery are, *first*, its 'depressing influence' kept up by nausea and vomiting, and, *secondly*, that it is liable to set up 'uncontrollable vomiting.'

First, the depressing power, nausea, and vomiting have all been over-estimated. Nausea is only a temporary and evanescent effect. Vomiting is an exceptional occurrence; and even when it does supervene, it seldom lasts long. As much nourishment, therefore, as may be required to support the strength can be allowed in the intervals between the large doses of ipecacuanha. But what contributes more to the conservation of the patient's stamina and to the prevention of depression or anæmia, is the speedy cessation of the dysenteric process accomplished by the drug, followed by refreshing sleep and the power of digesting and assimilating nourishing food. Such remarkable results as these soon reconcile any patient suffering from dysentery to an otherwise disagreeable remedy.

Secondly, when uncontrollable sickness and vomiting succeed the employment of this drug in the manner already recommended, the existence of one or other of the serious conditions previously enumerated may be more than suspected. In the absence of these complications, unmanageable vomiting is seldom if ever witnessed. Hence, in a preponderating majority of the cases of dysentery met with this objection is quite untenable. The truth is that every physician who has used ipecacuanha in heroic doses soon learns that depression of the vital powers from it is not to be feared, and is surprised at the small amount of vomiting that follows its administration, and at the unexpected ease with which the stomach tolerates its presence.

When dysentery becomes *chronic* no time should be lost in counselling removal from a malarious to a non-malarious and mild climate. A sea voyage—provided easily digestible food can be secured—is often attended by the happiest results. To men so afflicted 'the salt ration,' as remarked by Dr Maclean, 'is simply destruction.' The clothing should be warm, and flannels always worn around the abdomen; Dr. Maclean also recommends 'the use of a water belt over the abdomen for some hours daily. This acts as a fomentation, and the steady uniform pressure it maintains seems to favour the absorption of the fibrine effused between the intestinal coats. If there be much uneasiness about the fundament, a water compress over the anus affords more relief than opiate enemata.' The food should be chiefly concentrated soups, milk and lime-water, and sago, cornflour, arrowroot, &c., egg-slip with port, sherry, or brandy; or, if solid food can be digested, the tenderest chicken, lamb, or mutton, with bread and biscuit, may be allowed. Beyond sitting in a carriage or chair, no

exercise should be attempted. The position should generally be recumbent or semi-recumbent. The erect position excites peristaltic action, and thus disturbs the physiological rest required to facilitate the repair of the ulcers. Antiseborrhœic juices should be given where there is the least taint of scurvy or purpura. Frequent blistering does much good. All forms of counter-irritation are beneficial.

Gallie acid, acetate of lead, sulphate of copper, nitrate of silver, are reputed to act beneficially. Dr. Macclean's favourite remedy, 'particularly in men returning from tropical regions, anæmic from loss of blood and the depraving influence of malaria, is the solution of the pernitrate of iron. Under this remedy the whole system often rallies wonderfully, the condition of the blood improves, colour returns to the blanched cheek, the stools become more natural and less frequent, the appetite improves, and digestion is more perfectly performed. The citrate of iron and quinine may after a time be substituted.' As nearly all chronic cases are underlain by a malarious taint, quinine should form an important element in the therapeutic management, and the greatest care should be taken to secure for the residence of the patient a climate at once mild and temperate and free from suspicion of malaria. Bathing during convalescence is an efficient and welcome auxiliary. Tepid or warm baths medicated with Tilden's sea-salt or with nitro-muriatic acid act in stimulating the secreting function of the skin. But it will often happen that, in spite of the most careful dietetic, hygienic, and therapeutic management, no substantial progress towards the repair of the ulcers is made, and the patient eventually dies, worn out from suffering and the asthenia consequent literally on inaction.

JOSPH Ewart.

DYSIDROSIS (δύς, with difficulty, and ῥῆσις, sweat).—This is a disorder of the sweat-follicles hitherto confounded with eczema, and first differentiated therefrom and accurately described by the writer. It occurs in winter as well as in summer, and often in those who perspire freely, and it attacks the hands chiefly, and especially the interdigital and the palmar surfaces. The disease is characterised by the development of vesicles, which are not formed in the usual way in the rete, but are distensions of the sweat-apparatus by sweat secreted in excess, and which fails to find its way outward free upon the surface. These sweat-vesicles are at first situated beneath the level of the skin, and indeed appear as little boiled sago-grains imbedded deeply in the substance of the skin, and when once seen are readily recognised again. If pricked a little sweat oozes out. In the earliest stage the reaction of the fluid may be acid, but it soon becomes alkaline from admixture of serosity. These vesicles are distinct the one from the other at first, and are scattered about the interdigital surfaces or the palms, or they may be grouped. In some cases their fluid contents dry away, and a little dryness and perhaps slight degeneration follow. They may enlarge and become prominent upon the surface, or run together into bullæ, and if the sweat secretion is free, large

bullæ may form. Usually the cuticle becomes white and opaque from maceration in the fluid which collects beneath it, and subsequently it peels off in a membranous manner, leaving behind, however, a dry reddened surface, but not a discharging one as in eczema. One or both hands may be affected, and the feet may also be attacked. The disease occurs in connection with nervous debility. It may be attended with much itching or burning pain, and may be accompanied by miliaria.

ANATOMICAL CHARACTER.—If a portion of skin be excised and examined in the early stage of the disease, it will be observed that there is no true dermic inflammation, but that the morbid changes are limited to the sweat apparatus, as the writer has shown (*Pathological Society's Transactions*, 1879). The sweat-gland-coils are congested, and the results of such congestion are also seen in the duct-walls as they run upward to the Malpighian layer, where the vesicles are formed. In the early condition the sweat-ducts are dilated, and choked by epithelial debris, and gradually this portion and the rete layer immediately outside the ducts, dilate into vesiculations under the pressure of the fluid poured out into the tube. In later stages the effusion is so free, and the distension of the tissues so decided, that the nature of the original formation of the vesicles is not recognised, and the vesicles may simulate those of eczema, save that the amount of inflammatory products is less, and there is no distinct connection between vesicles and engorged papillary vessels beneath. In the earlier stages of the vesicles, however, ducts can be distinctly traced entering the vesicles from above and leaving them from below, which conclusively proves that the vesicles are formed in connection with the sweat-apparatus.

TREATMENT.—This consists internally in exhibiting diuretics, to be followed by nerve tonics according to circumstances, and locally in the use of soothing and astringent applications.

TILBURY FOX.

DYSMENORRHOEA (δύς, with difficulty, μήν, a month, and ῥῆσις, I flow).—Difficult and painful menstruation. See MENSTRUATION, Disorders of.

DYSOREXIA (δύς, with difficulty, and ὄρεξις, the appetite).—An obsolete term for impaired or depraved appetite. See APPETITE, Disorders of.

DYSPEPSIA (δύς, with difficulty, and πέψις, I concoct).—A synonym for indigestion. See DIGESTION, Disorders of.

DYSPHAGIA (δύς, with difficulty, and φάω, I eat).—Difficulty in swallowing. See DEGLUTITION, Disorders of.

DYSPHONIA (δύς, with difficulty, and φωνή, the voice).—Difficulty in producing vocal sounds, so that the voice is more or less enfeebled. See VOICE, Affections of.

DYSPNŒA (δύς, with difficulty, and πνέω, I breathe).—Difficulty of breathing. See RESPIRATION, Disorders of.

DYSURIA (δύς, with difficulty, and οὐρῶ, I pass water).—Difficult or painful micturition. See MICTURITION, Disorders of.

EAB, Diseases of.—The natural division of the ear into external, middle, and internal, suggests a rational, as well as a convenient classification of the disorders to which the auditory apparatus is liable.

1. **EXTERNAL EAR.**—In examination of the external meatus and tympanic membrane, bright diffused daylight, or, when this is not obtainable, light from a bull's-eye lamp lit with gas, is the best for illumination, and the light should be reflected from a concave perforated mirror of eight-inch focus down a tubular speculum. In any operative proceedings the mirror should be worn on the forehead, as in examining the throat, but otherwise should be held in the hand. As great variations in the calibre of the auditory meatus are met with, it is necessary to be provided with specula of several sizes, the most convenient form being that known as Gruber's.

Of the affections of the external ear the most important are the following:—

1. **Eczema.**—Although the acute form of eczema occasionally affects the auricle and external auditory meatus, it is far more common to meet with the chronic variety. Elderly females are especially subject to eczema of the ear, and it is its long continuance that the remarkable narrowing of the external meatus throughout its whole extent, met with occasionally in the subjects of this complaint, is generally attributable. Such narrowing will often amount to almost complete closure, and it is in these instances that eczema becomes the cause of greatly impaired hearing, for when this condition is arrived at, the passage down to the tympanic membrane is at times so small as only to admit of a very small probe. It is for this reason that, although no special methods of treatment are called for, beyond what is necessary when parts other than the ear are affected with eczema, it is of the greatest importance to keep the meatus sedulously free from secretion, and this occasionally is not a very easy matter.

- 2 **Changes in cartilage.**—Another condition, in which the external passage becomes subject to partial closure, is shrinking of the cartilaginous part of the meatus. This again, is a complaint of old age, and is attributable to no known cause. It is readily relieved by the patient wearing a piece of silver tube, to keep the passage patent.

- 3 **Bony growths** in the osseous part of the canal present two entirely distinct phases: one in which, beyond the enlargement of bone, there is no discoverable disease, and no impairment in hearing power, the other where the growth would seem to owe its origin to some irritation.

In the first case, the enlargements are very frequently symmetrical in either ear, and synchronous in their growth. So exactly is this so, that often where they exhibit three curves in one part of the bony canal on one side, the curves will be found to be precisely similar in size and position in the other ear. As the enlarge-

ments are not attended with pain, the patient will obviously be quite ignorant of his condition, until his attention is directed to one ear by a slight accumulation of cerumen, which will suffice to obstruct the passage of sound to the tympanum.

In the other example alluded to, disease of the tympanum precedes the so-called exostosis, and a perforation of the tympanic membrane, attended with a purulent discharge, will be present perhaps for some years before the growth of bone is discovered. It is in such a case that sometimes the exostosis, by preventing the escape of pus, becomes the indirect cause of death due to cerebral abscess. This is especially so where, in addition to the exostosis in the meatus, there is a polypus growing from the tympanic cavity.

TREATMENT.—With this complication, or where the meatus becomes completely closed, and in those two cases alone, it occasionally becomes imperative to remove the bony growth. The position of the tumours, and their extreme hardness, make this no simple task, and (except in the instance mentioned by the late Mr. Syme, when they were exceptionally friable) their removal has been attended with great difficulty.

Up to the present time two modes of proceeding have been the most successful. The first of these is as follows.—Two needles being inserted into the base of the growth, holes having been drilled for this purpose, the continuous current derived from ten to twenty pairs of plates (Stoller's battery) is then passed through them for a few minutes, and in the course of about six weeks the bone thus destroyed has become loose, and is readily removed with forceps. The second method consists in grinding the bone away by means of a drill, now in common use with dentists. Either proceeding is attended with so much pain that an anæsthetic is necessary.

4. **Inflammation.**—The external auditory meatus is subject to inflammation, diffused or circumscribed, the latter occurring in the form of small abscesses or boils. Both affections are attended by acute pain, and in each the general health of the patient has been out of order for some time previous to the local trouble.

TREATMENT.—Treatment in the direction of improving the general health; and local bleeding by means of leeches applied in front of the tragus, will often rapidly relieve the diffused form of inflammation, but when it has continued for a long period (as it not infrequently does), in addition to the soft tissues the periosteum becomes affected. The passage then throughout its whole extent becomes so swelled as to nearly close the external opening, and pain is constant. The only treatment which gives complete and permanent relief under these circumstances is to make two or three free incisions down to the bone, along the whole extent of the osseous part of the canal. A convenient instrument for this purpose is a small sharp-pointed curved bistoury. As to the propriety of opening

abscesses in this situation there can be no question, for, owing to the extreme denseness of the tissues and their approximation to bone in the external auditory canal, abscess in this part is slow in its progress and attended with very great suffering. These abscesses being especially liable to recur, a proper regimen and medicines appropriate to the failure in general health are required.

5. *Fungi*.—The external auditory meatus has been occasionally found to be the seat of two varieties of vegetable fungus, namely, *Aspergillus flavus* and *negricans*. The symptoms which they have given rise to have been great irritation, and a slight discharge. They have been readily destroyed by syringing, and the local application of spirits of wine.

6. *Polypus* of the ear is usually preceded by inflammation in the tympanic cavity and perforation of the membrane, and is considered along with diseases of the middle ear.

7. *Hæmatoma Auris*. See *HÆMATOMA AURIS*.

11. *MIDDLE EAR*.—All affections of the middle ear originate in some part of that tract of mucous membrane which, commencing where the Eustachian tube opens into the pharynx, forms the lining of this tube, and of the cavity of the tympanum, finally becoming the innermost layer of the tympanic membrane. To the character of this tissue is due the term catarrh, which, in its two forms of purulent and non-purulent, is used in describing any deviation from health which, directly or indirectly is the cause of pathological change in the Eustachian tube or tympanum.

1. *Obstruction of the Eustachian Tube*.—One of the most frequent conditions under which the Eustachian tubes become the seat of obstruction is that met with in children or young persons. The subjects of this affection present a very characteristic aspect. They breathe almost entirely through the mouth, which, sleeping or waking, is kept partially open; their tonsils are often enlarged, and they snore loudly during sleep. The mucous membrane of the nares and pharynx is swollen, and secretes in excess; owing to this tumid state of the tissues the passages to the Eustachian tubes in this situation do not admit of the constant necessary supply of air to the tympanum. The air in these cavities undergoes partial absorption, and thus becomes more rare than that external to the tympanic membrane, the density of the outer air remaining the same, the equilibrium from pressure is destroyed, the membrane, consequently, is retracted, the chain of ossicles are pressed inwards, and thus the conduction of sound becomes interfered with—in short, the patient is more or less deaf. In these cases inspection of the tympanic membrane at once reveals the state of affairs. As the cavity of the tympanum is not involved in the catarrhal change its translucency and lustre are not impaired, the handle of the malleus is tilted upwards, the head of this bone is unusually prominent, and there is a distinct fold crowing the upper part of the posterior section of the membrane. Where the obstruction has lasted for a long period, the membrane will appear to be almost fallen in upon the walls of the tympanum, and the pro-

montory and incus may be distinguished. If under these conditions the tympanum be inflated on Politzer's plan,¹ an instant return to good hearing follows, but in the course of a few days the improved hearing partially dies away, leaving the patient, however, in some degree better than before the operation.

TREATMENT.—This should be twofold. In the first place the tympanum should be regularly inflated, and this may be practised at first every three or four days, and gradually at longer intervals. Secondly, astringent applications should be applied to the pharynx. Of these applications one of the best is a solution of perchloride of iron, 2 drachms to 1 ounce of water, and it should be used daily by means of a curved camel-hair throat-brush. When the nares are much obstructed great benefit will follow the use of saline solutions through the nasal douche, or they may be insufflated, that is, drawn up through the patient's nose into the pharynx and then spat out.

If the tonsils are so much enlarged as to interfere with the respiration, it will be necessary to remove them, but the reason for this proceeding is not that they press upon the opening of the Eustachian tube, but because their presence keeps up the unhealthy condition of the pharynx.

Under this routine of treatment the patients completely recover their hearing, the space of time during which it is necessary to continue treatment varying according to the obstinacy which each case manifests.

Obstruction of the Eustachian tubes in *adults* presents certain well-marked differences from the affection as it prevails in *children*. An ordinary cold is the beginning of the trouble. It is more usual to find one instead of both tubes obstructed, and more often than not the tympanic cavity is involved in the catarrh. Where this is not the case—and it will be evident from the retained lustre and transparency of the membrane—the same principles of treatment as are pursued in the case of children will hold good, except in so far that the affection in grown-up persons is less persistent after the tube has been once artificially opened, and that, to effect this, Politzer's method is sometimes not sufficient, or, even if so, not as efficacious as the Eustachian catheter. It must also be borne in mind that in the treatment of cases in which one ear is healthy, by means of the catheter the affected ear exclusively may be subjected to the air-douche, whilst with Politzer's method it is impossible to avoid forcing a stream of air into the healthy tympanum, and this is not always an advisable proceeding.

The Eustachian Catheter.—The following is the mode of using the Eustachian catheter:—Place the patient in a chair, and let him lean back, steady his head with the left hand firmly fixed on the top of it, hold the catheter lightly in the right hand, with the curve downwards.

¹ This method of inflating the middle ear (now in such general use) consists in passing a stream of air from an india-rubber bag through one nostril whilst the patient swallows some water. The operator at the same time closes one nostril with the forefinger of the left hand, and completes the closure of the other with the thumb. The mouth must be kept firmly shut.

and pass it quickly in this position through the inferior meatus of the nose to the posterior wall of the pharynx. When this is felt, withdraw the catheter about half an inch, and tilt the point of the curved end rather upwards, and to the left or right, according to the side which is being operated upon. Now hold the catheter and end of the patient's nose steadily between the thumb and the first two fingers of the left hand. All this time the ear of the patient and that of the surgeon are connected with the otoscope. The point of the catheter is now supposed to be in the pharyngeal orifice of the Eustachian tube, but the only certain sign of this being the case is that when air is forced into the catheter it will be heard through the otoscope to impinge upon the tympanic membrane when a stream of air is passed down the catheter.

The catheter may be made of silver or of vulcanite, but of whatever material, it must be inflexible whilst being used. Beyond this, suffice it to say here that in practised hands its employment is invaluable, and indispensable in the treatment of most affections of the middle ear, not only in overcoming obstruction of the Eustachian tube, but also as a means by which injection of fluids may be applied to the cavity of the tympanum. In making use of the air-douche an indiarubber bag fitted to the catheter should be employed, and in using injections to the tympanum a similar arrangement is necessary.

2 Catarrhal Inflammation of the Tympanum.—When the tympanic cavity has become involved in the catarrhal state, or when the affection, instead of proceeding up the Eustachian tubes, begins in the tympanum, as it frequently does, those changes have commenced which, of all others, form the most frequent impediments to the conduction of sound—in other words, which make the subjects in which they are found more or less deaf, and it may be broadly stated that the extent to which this affection is remediable depends directly upon the time at which the patients suffering from it apply for treatment. In the early stages, the obstruction to the passage of sound through the tympanum is solely due to the effusion of mucus in this situation, and this is easily demonstrated by the moist gurgling sound which inflation of the tympanum produces, as may be heard upon connecting the ears of the patient and surgeon by means of a piece of indiarubber tubing. Afterwards comes what may be termed the dry stage, i.e. when the fluid portion of the mucus has suffered absorption, and when any of the products of inflammation may have become more or less organised, or at least in a condition which, if not interfered with, suffers no further change. The morbid conditions which result from non-purulent catarrh of the tympanum are twofold. First, those which affect the tympanic membrane, and are, therefore, demonstrable during life; secondly, those which are met with after death in the tympanic cavity. The first of these include changes in curvature, in colour, and in consistence.

The slighter changes in curvature have been

¹ This tubing should always be used, whether air or fluids are being injected through the Eustachian tube, for upon the sounds thus heard as well as on the patient's own perception, the answer to the question whether the inflation is complete depends.

noticed in speaking of obstruction of the Eustachian tube, which condition is necessarily more or less present in all cases where the tympanum has been the seat of catarrh, and these changes are met with indefinitely increased until the state of complete collapse is reached.

In this condition the membrane has the appearance of being in close apposition to the walls of the tympanum, and lapped round the ossicles so that the forms of the malleus, incus, and sometimes the stapes are distinctly traceable.

In so extreme an example, the membrane is generally bound down to the tympanic wall by adhesions. The first change which the membrane exhibits is a loss of its lustre and transparency, it becomes opaque. Further alterations in colour, in cases of long standing, consist in the formation of patches of brown, yellow (colour of parchment), and white. Variations in consistency will include thickening throughout the membrane, or in parts of it, especially in the cases of dense chalk deposits (phosphate of lime); and thinning in places, so observable sometimes that inflation will induce bladder-like protrusions, which, as inflation is suspended, fall back again; changes in all these respects completely metamorphosing the appearance of the membrane. After death, within the tympanum may be found collections of dried mucus around the ossicles; thickening of the lining membrane, bands of adhesion in all directions; and anchylosis of the ossicles to each other, as well as between the stapes and fenestra ovalis.

As additional evidence during life of obstruction in the tympanum, it may be mentioned that sounds from a vibrating tuning-fork placed on the vertex are intensified when such obstruction exists, and the nerve remains unimpaired; this test is especially valuable where one ear is healthy, inasmuch as the sound will be heard exclusively on the deaf side, thus being due to the fact that vibrations of sound thus conveyed to the auditory nerve, on their passage outwards through the tympanum, meet with the obstruction in this position, and are reflected on to the labyrinth. The appearances above described, together with the history of the case, serve sufficiently to distinguish affections of the conduction from those of the nervous apparatus, and the sounds which are produced upon inflation of the tympanum, whether of a moist or dry character, give evidence as to whether the mucus in the cavity of the tympanum is in a moist or less fluid state, or has reached the dry stage where the fluid part of the secretion has become absorbed, the more solid portion remaining.

In the first of these conditions, the inflation at once increases the hearing power; in the second, it produces no change in the hearing. An indication in this direction is a most useful guide in respect of treatment, for whatever differences in opinion may exist as to details in relation to this subject, experience has amply shown that the injection of fluids into the tympanum is for the majority of cases the treatment of all others the most successful, and, speaking generally, it may be said that when the sounds which accompany inflation of the tympanum are of a moist character (showing that undue secretion from the mucous membrane is going on), astringents, such as syl-

plate of zinc, 1 to 2 grains to the ounce of lukewarm water, will be found most efficacious, and that when the dry stage has been arrived at, alkaline solutions—bicarbonate of soda or potash, 5 grains to the ounce, or still better an injection containing hydrochlorate of ammonia, 5 grains to the ounce—should be substituted.

Injecting the Tympanum.—There are three modes of injecting the tympanum, and their order of efficiency stands as follows:—Firstly, when the Eustachian catheter has been placed in position a few drops of the injection are introduced into it from a small glass syringe, and forced into the tympanum by means of an indiarubber bag, the nozzle of which is made to fit the open end of the catheter. Secondly, a few drops are placed in the inferior nares, on the same side as the ear under treatment, and injected in front of a stream of air blown to the tympanum on Politzer's plan. the patient's head being inclined to the side to be acted upon. Thirdly, the fluid being arranged in precisely the same way, the patient forces it up the Eustachian tube by attempting to blow through the nostrils, whilst the mouth and nose are closed.

The injection may with benefit generally be repeated every other day for from two to four weeks, but for this no rule can be laid down which would apply in every case.

Such is the briefest outline of the treatment under which these cases recover in greater or less degree. The degree of improvement varies within wide limits, but the greater benefits may always unhesitatingly be predicted during the moist stage of the catarrh. Indeed the necessity for early treatment is abundantly shown, in the instance of catarrhal affection of the middle ear, by the extremely satisfactory termination of cases treated early in the disease, and the slight relief which but too often follows when the affection has been allowed to proceed for years unchecked. In such cases as the latter, the fact that considerable quantities of inspissated mucus have been found in the tympanic cavities first suggested the operation of making an incision into the tympanic membrane, and attempting the removal of mucus through the incision by passing a stream of air through the tympanum. This proceeding, with certain modifications afterwards introduced, is no doubt very useful in cases favourable for its employment, but it should be reserved for those which have defied the less severe means, and where there is unmistakable evidence of an obstruction to the passage of sound through the tympanum. Experiments with the tuning fork, already referred to, give valuable evidence in this direction, but for a detailed account of this method of treatment, introduced some years ago by Mr Hinton, the reader is referred to *Questions of Aural Surgery*. Suffice it to say here that an incision about one-eighth of an inch in length is made in the posterior section of the membrane with a catarract-needle, and this is followed by passing a stream of fluid (a weak solution of soda) through the tympanum and Eustachian tube by means of a syringe made to fit the external meatus. In appropriate cases it is often undoubtedly of very great service, and is neither a dangerous nor a harmful proceeding so long as there is no nervous

complication, where, however, this is present surgical interference has at times proved most disastrous.

Another operation, performed by Dr. Weiler of Berlin, consists in the division of the tensor tympani muscle, but up to the present time the results at the hands of others do not warrant it as a recognised operation for the relief of conditions in being deafness.

3 Purulent Catarrh of the Tympanum — Perforation.

—The form of tympanitis in which the effused fluids become purulent, is an acute and generally an extremely painful affection. Usually the pus rapidly makes its escape from the tympanum into the external meatus, by a process of ulceration through the tympanic membrane, leaving as its result a perforation of this structure. In quite the early stage the affection may often be cut short by the free application of leeches in front of the tragus, followed by fomentations but more often than not the membrane has given way before the patient comes under observation. Even then, if the tympanic cavity be emptied of the pus by the free use of Politzer's inflation and repeated syringing, the opening will often close, and leave very little, indeed sometimes hardly any appreciable deafness. If, however, a purulent discharge through the opening be allowed to go on unchecked for any length of time, it is the exception for the perforation to heal. This condition is constantly seen after scarlet fever, measles, or any of the exanthemata. A perforation of the tympanic membrane presents an infinite variety of aspects, from a small pin-hole to nearly complete loss of the membrane, but there will always be a slight remaining external rim of membrane. This latter is perhaps the most frequent of all forms of perforation, and especially when the ulceration dates from an attack of scarlet fever. Although the handle of the malleus occasionally remains, it more usually comes away in these and other cases where the loss of tissue is very extensive. The head of this bone, however, may always be distinguished, unless there has been complete disorganisation of the tympanic cavity. Among other forms of perforation commonly met with may be mentioned those in which the anterior or posterior half of the membrane is left, and is bounded internally by the handle of the malleus; the so-called *reniform* perforation, where the lower part of the membrane is lost and the umbo of the malleus indicates the position of the hilus of the kidney; and the small, smooth-edged circular perforation which is common alike to all parts of the membrane. Occasionally, though not very often, the tympanic membrane is the seat of a double perforation. Similar variations in hearing accompany this condition, between slight deafness and total loss of hearing power. The size of the perforation affords no guide in this respect, extreme loss of hearing being met with when the perforation is very small, and very slight deafness where the loss of tissue has been most extensive, so that it may be unhesitatingly stated that the loss of the membrane is but in a very small degree the cause of the deafness in these cases, the disorganisation in the tympanic cavity mainly accounting for this. Such disorganisation is at times so com-

plets (especially after scarlet fever) as to include the loss of all the ossicles, total deafness, and paralysis of the muscles supplied by the portio dura. A very small perforation in the anterior and superior part of the membrane may from its position escape notice, but the diagnosis can be always verified by the facility with which air may be made to pass through the opening, or the reverse, provided that the communication between the Eustachian tube and the tympanum is not closed by cicatricial tissue—a very rare condition when so little of the membrane has suffered ulceration.

TREATMENT.—The treatment of purulent tympanitis and perforation will include assiduous cleanliness, keeping the Eustachian tube free from obstruction, and the use of astringent injections. When the exposed surface of the tympanum is covered, as it sometimes is, with exuberant granulations, much benefit will be derived from the application of solid nitrate of silver to the granular surface, care being taken not to touch any other part. As the condition of the ear improves under these measures, so will the hearing power vastly increase when it has not been completely lost, but there still remains the oftentimes invaluable application of what is spoken of as the *artificial membrane*. Of all kinds, the best undoubtedly is the flattened pad of moistened cotton-wool, applied by the patient, every morning, with a pair of forceps constructed for the purpose. Until this be tried in each case it is impossible to say whether it will do good, but when it is useful—as it is in a large number of cases—by its help the patient will recover very good hearing, and this even when the perforation has existed for a period of many years. That its effects depend upon the support which it gives to the ossicles, thus re-establishing the normal pressure of the stapes upon the fenestra ovalis, has been unquestionably demonstrated.

4. Polypus.—One of the most frequent complications in cases of perforation of the tympanic membrane is polypus, a term employed to designate a fleshy tumour in the ear. Although polypus are occasionally present in the meatus independently of perforation, the most usual situation from which they arise is the lining membrane of the tympanum. Sometimes the exact point of origin is the edge of a perforation, and still more rarely the sides of the meatus. In size these growths vary from a small protrusion through a perforation to a tumour which entirely fills the meatus and projects externally from the ear. In this latter instance the growth presents a very distinctive appearance not unlike a raspberry. Sections of aural polypi hardened in chromic acid with few exceptions show the structure to be fibro-cellular, the fibrous element preponderating over the cellular in proportion to the age of the tumour.

TREATMENT.—In all cases polypus should be removed, and the best instruments for this purpose are the rectangular ring polypus forceps, or, in the case of a large growth, a Wilde's snare. Owing to their remarkable tendency to recur, removal is only the preliminary step in treatment. The principal part of this consists in their complete eradication by caustics. Of these the most efficacious and convenient is chlor-acetic acid, and later in

the treatment nitrate of silver. The acid may be applied on a very small camel's-hair brush, or on the point of a probe defended by a small twist of cotton wool, and a convenient form of nitrate of silver is a bulb of the melted salt fused on to a probe or platinum wire. The caustic should be applied daily for some time after the polypus has been removed, and then less frequently. The treatment should also include the same scrupulous cleanliness and application of astringents, so desirable in the case of perforations. It is simply to the want of attention to details that failure in the treatment of aural polypus may be ascribed.

COMPLICATIONS OF TYMPANIC DISEASE.—*a. Facial Paralysis.*—This is due to inflammation around the portio dura in its passage through the aqueduct of Fallopius. When suppuration in the tympanic cavity, with caries of the bony canal, precedes or accompanies the loss of function in the nerve recovery is hopeless; but when the paralysis follows a subacute entarrh of the tympanum, not ending in a perforation, as is sometimes the case, the paralysis in time disappears no less certainly than when it is dependent upon an affection of the nerve at a point after its exit from the temporal bone.

b. Pyæmia Cerebral Abscess; and Meningitis. When the mastoid cells become the seat of inflammation, the pain, tenderness, and pitting on pressure over the mastoid process, will at once suggest an early incision down to the bone, and it may be truly said that this is often delayed too long, and perhaps is never done too soon. Again, when the symptoms point definitely to pus within the mastoid cells, the bone should be pierced so as to make the external opening communicate freely with the cells. Relief given in this way will occasionally be the means of saving life, by preventing the absorption of poisoned material into the lateral sinus. Besides pyæmia thus induced, other fatal issues which suppuration in the middle ear frequently entail have their starting point in the tympanic cavity, and in such instances cerebral abscess or meningitis may be the immediate cause of death. In the latter case a post-mortem examination reveals pus in the arachnoid cavity, or between the roof of the tympanum and the dura mater, in the former, the seat of the abscess may be either in the cerebrum or cerebellum; this portion of the brain (the cerebellum) being more generally, though not always, the part affected when the mastoid cells are involved as well as the tympanum.

The pathology of cerebral abscess, as a result of ear-disease, cannot with truth be said in all cases to be completely explainable, and this for the following reason:—Whilst in most cases a distinct communication can be traced between the diseased roof of the tympanum and the seat of the abscess, in a few the most careful examination fails to show any connection between the two, the abscess being separated from the bone by healthy brain-tissue. Occasionally, no disease can be detected in the bone itself, and this even after the bone has been macerated and sections of it made.

Fatal terminations of this nature most frequently occur when cleanliness and local treatment of the ear have been neglected. Hence the necessity for such care.

But the fact that even under the most favourable conditions such events are possible when there is a fistulous opening in the tympanic cavity should induce caution with insurance offices in taking the lives of persons with this lesion, at the ordinary premiums. Fatal cases of this kind might seem in practice to be almost divisible into two classes, namely, those in which cerebral symptoms come on soon after the establishment of the perforation; and others where there has been a purulent discharge from the ear (that is, from the tympanum) for many years before the advent of such symptoms. In this latter class must be included those cases in which the temporal bone has become the seat of caries; and it may be stated, subject to no exceptions, that whenever exposed bone can be detected by means of examination with a probe within the cavity of the tympanum, the subjects of this condition are always more or less in a perilous state, and that at any time fatal symptoms may commence with a severe rigor, the earliest of all succeeding symptoms. For this reason, even when exposed bone cannot be absolutely demonstrated in the way mentioned, the existence of bone-granulations where there is a perforation of the tympanic membrane should be regarded as a most serious complication. The same danger, though in a very much less degree, may be said to be present when dead bone can be detected in the mastoid process—in a less degree because the outer table of the bone is often affected whilst the inner remains healthy. The dead bone then in the former position becomes exfoliated, and the external wound heals. Such are briefly the points of importance in connection with caries of the temporal bone. How caries of the mastoid process may be obviated by a timely perforation of the mastoid cells, and how the chief part of the temporal bone may when carious be removed and the patient survive, may be seen on reference to a paper entitled 'Disease of the Mastoid Bone' by the writer of this article in the *Transactions of the Medical and Chirurgical Society* for 1879.

c. Malignant Disease.—In the paper just mentioned is also reported a case of malignant disease of the ear, in which the cavity of the tympanum, having been the seat of suppuration for some time, became affected with epithelial growth, which caused the death of the patient. From all recorded cases of malignant disease of the ear it would seem that the seat of origin of the new-growth will be found to be the lining membrane of the tympanic cavity, and that a purulent discharge from this surface always precedes the appearance of the cancer, and must therefore be regarded as the exciting cause of the growth. In its early stages cancer in this situation bears a strong resemblance to the ordinary forms of polypus. The same cause, then, which in some cases calls into being a polypus may occasionally give rise to malignant disease, and this without any predisposing cause (so far as can be ascertained) in the patient towards cancerous growth.

III. INTERNAL EAR.—Apart from deafness due to local changes in the external or middle ear, the function of hearing is subject to impairment from causes which have their seat in the nervous structures of the ear; in other words,

although the conduction of sound may be good, the perception of sound may be faulty. The inability to hear the vibrations of sound conveyed through the cranial bones, such as from a vibrating tuning-fork placed upon the vertex, is indicative of this condition. For the rest, the absence of tympanic disease, and the history of the case must supply the evidence required for a diagnosis. Familiar examples of this nature are the deafness which often accompanies old age, or which is left after fevers when the middle ear has not suffered; the two forms of syphilitic nervous affection mentioned below; the sudden and sometimes total loss of hearing which occasionally follows a severe mental shock, the deafness after loud explosions near the ear, so common in artillery-men and naval men; and that which is caused by blows on the head and boxes on the ear. An attack of mumps will sometimes leave behind an irremediable loss of hearing in one or both ears, unattended with any discoverable change in the tympanum. In a similar way weakly women occasionally become more or less deaf during their confinement, and this symptom becomes aggravated when each successive child is born. In connection with this subject, prolonged suckling may be mentioned as one of the numerous debilitating causes which undoubtedly aggravate the trouble of an already impaired ear.

Among the nervous affections of the auditory apparatus possessing certain characteristics which serve to distinguish it from others is the so-called *Menière's disease*, an attack of which at times gives rise to symptoms which would be alarming if their true origin passed unrecognized. A patient who suffers in this way is seized with an attack of vertigo so severe that he not infrequently falls, and for some hours afterwards requires assistance in walking, occasionally vomiting succeeds the giddiness, and he recovers to find himself very deaf in one ear, with which previously he had heard well. Milder attacks of the same nature generally follow the first, and each one leaves the patient more deaf. Although the presumptive evidence is in favour of the theory that the seat of morbid changes in *Menière's disease* is in the semi-circular canals, up to the present this point has not been quite satisfactorily determined. No treatment appears to exercise any influence upon the disease.

SYPHILIS.—The affections of the ear due to syphilitic disease demand separate consideration, and they occur under the following varieties:—Firstly, in the form of sores and warts in the external meatus, which yield to local treatment. Secondly, affections of the middle ear during the secondary ulceration of the throat, the treatment for which, beyond specific medicines, in no way differs from what is useful in the ordinary catarrh of the same parts. Thirdly, failure in hearing power during the secondary stages, unattended with any change in the middle ear. This disappears under constitutional remedies. Fourthly, the loss of function in the auditory nerve, so commonly met with in the subjects of inherited syphilis. In these patients the hearing power begins to fail between five and fifteen years of age (very seldom later in life); and proceeds to very great and often total deafness, the period between good hear-

ing and the extreme point of deafness arrived at varying from a few weeks to several years. From this cause children sometimes become in the course of a month or six weeks totally deaf, but such rapidity is exceptional. Experience has shown how powerless treatment is to arrest the progress of this affection, so that attention should be confined to preventing its subjects from becoming dumb, if they are attacked after they have acquired speech and before they are likely to forget it, viz. from about four to seven years of age. This is best attained by teaching them lip-reading, and if they can read, by making them do so (*adroit*) several times each day. In this way a child will retain its recollection of language when otherwise speech would pass away.

W. H. DALEY.

EAUX-BONNES, in France.—Sulphur waters. See MINERAL WATERS

EAUX-CHAUDES, in France.—Sulphur waters. See MINERAL WATERS

EBURNATION (*ebur*, ivory).—A state of bone-tissue in which it assumes the whiteness, smoothness, and hardness of ivory, in consequence of an increased deposit of calcareous matter. It occurs chiefly in rheumatoid arthritis. See RHEUMATOID ARTHRITIS.

ECBOLICS (*ἐκβολή*, abortion).—This name is given to the medicines that produce abortion. In moderate doses ecbole drugs act as emmenagogues. See EMENAGOGUES.

ECCHYMOSIS (*ἐκ*, out of, and *χυμός*, juice).—An extravasation of blood into the cellular tissue, due either to injury or to disease. It presents at first a more or less blue or bluish-black appearance, which changes with age, passing through green to yellow. See EXTRAVASATION.

ECHINOCCUS (*ἐχίνος*, a sea-urchin, and *κόκκος*, a grain).—This term, in its original generic signification, was employed by Rudolphi for the purpose of including several varieties of bladder-worm infesting man and animals (*Echinococcus hominis*, *E. veterinarius*, *E. granulosus*, &c.) These different bladder-worms are now collectively spoken of as *hydatids*, and all of them are known to be mere varieties of the common hydatid, which (as proved by the experimental researches first successfully instituted by Von Siebold, and subsequently verified by Hanlman, Kuchmeister, Lenekart, Nettlehip, and others) forms one of the larval or sexually immature stages of growth of a small tapeworm, normally resident in the intestinal canal of the dog and wolf (*Tænia echinococcus*). From a physiological point of view, a thorough knowledge of the mode of origination and development of the so-called echinococcus becomes most instructive, but a full exposition of the histological and other changes that accompany the metamorphoses cannot be given in this place. Practically, the term echinococcus has at length come to be employed in such a restricted sense as to refer only to the vesicles, or heads of the future *Tænia*, which are normally developed from the granular layer or internal membrane of the hydatid. Different opinions exist respecting the precise structural changes involved in their formation, but what is already known and accepted by helminthologists

is the result chiefly of the labours of Lenekart, Nauwyn, Rasmussen, Wilson, and Huxley. The clinical and hygienic bearings of this subject in relation to the so-called echinococcus-disease will be discussed elsewhere. See HYDATIDS.

T. S. COSSOLD.

ECHINORHYNCHUS (*ἐχίνος*, a sea-urchin, and *ῥύγχος*, a beak).—A genus of thorn-headed worms, belonging to the order Acanthocephala. Until the year 1857 there does not appear to have been a well-authenticated instance of the occurrence of this form of entozoon in the human body. In that year a young example (*E. hominis*, Lambil), was found, *post mortem*, in the small intestine of a boy, nine years of age, who died of leucæmia (*Trager's Vierteljahrsschrift*, 1859). This specimen measured less than a quarter of an inch in length. It has been supposed that the parasite was an immature example of *Ech. guana*, but this view has been disproved by Lenekart. Whether it be a new and altogether distinct species remains uncertain. The more recent instance alleged by Welch cannot be accepted as genuine, but must be referred to *Pentastoma*.

T. S. COSSOLD.

ECLAMPSIA (*ἐκλάμψω*, I flash, I explode).—This term is now used as a synonym for convulsions, whatever may be their cause. See CONVULSIONS.

ECPHYMA (*ἐκ*, out of, and *φύμα*, a swelling). A growth from the integument. The term was employed by Mison Good as a designation for warts and corns, but is at present almost obsolete.

ECSTASY (*ἔκστασις*, I amaze)—**DEFINITION.** The term ecstasy has been applied to certain morbid states of the nervous system, in which the attention is occupied exclusively by one idea, and the cerebral control is in part withdrawn from the lower cerebral and certain reflex functions. These latter centres may be in a condition of inertia, or of insubordinate activity, presenting various disordered phenomena, for the most part motor.

DESCRIPTION.—The subjects of ecstatic phenomena are commonly of the female sex, or are men who lead celibate and ascetic lives. To these individuals they are in the present day almost confined. In the middle ages, on several occasions, under special circumstances, an intense dominant emotion, with some attendant ecstatic manifestations, spread widely by a sort of moral contagion.

Women who are the subjects of this morbid state are usually single, frequently present menstrual irregularities, and often distinct evidences of hysteria, of which the ecstatic condition may be but a part. The immediate cause of the attack is usually some repeated vivid emotion, commonly religious, sometimes one of fear. The direction taken by the motor or other phenomena of the ecstatic state is often very obviously determined by imitation. With this are associated, in some cases, assertions of supposed facts, which transcend the ordinary course of natural phenomena, and which have been proved, in many instances, to depend on intentional fraud.

As forms of ecstasy we have the condition of

religious enthusiasts, who lose, in their one dominant emotion, all control over the other mental processes, and the latter may act in entire subordination to their religious feeling. Dreams and visions are determined by the ecstatic emotion, and add to its intensity. All consciousness of the body may be lost, so that all sensation may seem to be gone for a time; while the corporeal functions, ingestion and egestion, are reduced to a minimum, and a little exaggeration may represent them as in complete abeyance. Hence the 'fasting girls' of various countries, by whom 'stigmata' marks, in the position of the nails employed in crucifixion, are sometimes presented, probably by artificial production, possibly by the influence of the mental state on the processes of nutrition. In some hystero-epileptics a state of ecstasy—of rapt, intense emotion—forms part of the pyroxyal seizures, and then wild muscular spasms replace the tranquil repose of the more volitional ecstasies. Occasionally—when an intense emotion is shared by many persons—insubordinate muscular movements occur, of a rhythmical character, seen in the Jumpers and Shakers of the present day, and more strikingly in some of the dancing religious ceremonies of half-civilized races, and in the dancing epidemics of the middle ages. Such were the original dances of St. Vitus, in which the exciting emotion was religious, and the tarantella, in which the excitant was terror at the supposed consequences of the bite of the tarantula, which the dance was intended to avert.

TREATMENT.—It is rarely now that ecstatic manifestations have to be treated except as part of pronounced hysteria, and the treatment is that of the hysterical state which underlies the ecstasy. The measure of paramount importance is the substitution of a 'healthy moral atmosphere' for that under which the symptoms have arisen; and the exposure of actual fraud. Occasionally, even now, examples of solitary ecstasy come under observation. In these considerable care and tact are needed. Ecstasies are not amenable to the motives which influence most persons, and if there is actual fraud, will sometimes die rather than be found out. In the case of fasting girls, due observation of the body-weight during a short time will answer as well as, and is much safer than, a long exclusion of food. But the removal of the ecstatic to other surroundings is the most important step for both detection and cure. W. R. GOWEN

ECOTHYMA (*ecôthē*, I burn out)—A pustule or pimple; pathologically occupying a mid-place between a pustule and a furuncle. The so-called tar-acne, the small inflammatory pustules developed around a mother-boil, and the commoner eruptions produced by iodine and bromine, are examples of ecthyma. *See* SKIN, Diseases of.

ECOTPIA (*ek*, out of, and *trōps*, a place)—An abnormal protrusion or displacement of a part; for example, *ecotopia vesicæ*, protrusion of the bladder. *See* ORGANS, Displacement of.

ECOTROEA (*êvtrōs*, without, and *trōs*, an animal)—A term employed by some naturalists to embrace all the external parasites. *See* EPINA.

ECTROPION } *ek*, out of, and *trōps*, I
ECTROPIUM } turn?—A condition in which the eyelid becomes everted, so that the conjunctival surface is exposed. *See* EYE and its Appendages, Diseases of.

ECTROTIC (*êctropôikos*, I miscarry)—A term applied to arresting the course of a morbid process, for example, the development of small-pox. The agent by which the pustule is made to abort, namely, the ectrotic, may in this instance be a point of nitrate of silver. A coating of plaster, and especially substances which will exclude the light, such as mercurial ointment, or an ointment of lampblack, are likewise employed as ectrotics of small-pox.

ECZEMA (*êxēma*, I bubble up)—**SYNON :** *Fr.* *eczéma*, *Ger.* *Ekzem*.

DEFINITION AND GENERAL REMARKS.—Eczema is an inflammation of the skin, remarkable for a multiple series of pathological symptoms, and for extremes in degree of development and duration. It may be taken as the type of inflammation of the integument, and as an illustration of the varied pathological manifestations of the skin. As in other organs, the inflammation may be acute or chronic, may vary in severity and extent, and may occur at every period of life; but the special position and functions of the skin render the progress of eczema always uncertain and slow.

ÆTIOLOGY.—The proximate cause of eczema is hyperæmia. Every exciting cause giving rise to hyperæmia is capable of producing eczema, and if the tissue of the skin be weak will necessarily be the occasion of that affection. It is in this way that local irritants act on a susceptible skin, so as to produce eczema; such, for example, as heat and moisture, friction, mechanical and chemical stimulants, and obstructed venous circulation. It is in this way that a poultice, a water-dressing, a stimulating lotion, or the action of the sun or of a pungent atmosphere, may be the local cause of eczema. Constitutionally, disturbed nervous function, however induced, by producing disturbance of the circulation and nutrition of the skin, is among the commonest of the causes of eczema. The starting point may be malassimilation occurring at any period of life. malassimilation will act as a disturber of nutrition and circulation of the skin, and those pathological processes known as eczema will be the result. In this manner we may trace back the cause to disordered digestion, painful dentition, painful menstruation, pregnancy and parturition, or nervous shock; and we are led to the conclusion that feeble digestion, assimilation, and nutrition constitute a predisposing cause of general and cutaneous debility, which only requires the interposition of an exciting cause to become an eczema. That eczema is powerfully under the influence of the nervous system is shown by the sudden and sometimes periodical exacerbations of its symptoms, and their subsidence under the influence of agents which soothe and tranquillize the nerves. In the simplest form of expression eczema may be said to be a general as well as a local debility and to be induced and kept up by

every cause which tends to lower the life force of the organism.

Ecze^ma is specific neither in its nature nor in its cause. Every cause of irritation acting on a frame and on a tissue enfeebled by disordered function is capable of becoming a cause of this affection. It is hereditary only in the sense of the transmission of natural tendencies from parent to off-spring, and not by virtue of any special virus or *causa morbi*, and for a similar reason it is non-contagious. Nurses are occasionally affected with ecze^ma from contact with the acrid secretions poured out by the inflamed skin, but the same result would follow in an equal degree from contact under similar circumstances with any other kind of irritant fluid, the two essential factors of ecze^ma being a susceptible skin, natural or artificial, and the presence of an irritant. The warmth, the moisture, and the stimulation of the wash-tub are as active a cause of ecze^ma to a sensitive skin as the most profuse contact with eczematous discharge. And there is no more energetic generator of ecze^ma than the sun's rays when operating on the enfeebled integument of the victims of a city life.

SYMPTOMS AND VARIETIES.—The objective signs of ecze^ma are—redness, slight swelling, papulation, vesiculation, exudation, incrustation, desquamation, thickening, hardening, fissure or chapping, and the subjective sensations, burning heat, itching, and pain. The whole of these symptoms are not necessarily present at the same time, but they may all be in existence at once on different parts of the same person, and their separate preponderance is marked by distinguishing names, constituting the so-called varieties of Ecze^ma. Thus, for example, when the prevailing symptom is redness, the case is one of *E. erythematousum*, and may subside with simple desquamation. When the hyperæmia causes congestion of the follicles and their uprising in the form of pimples, the case is termed *E. papulosum*. With the moderate swelling or œdema which always characterises ecze^ma resulting from serous effusion, there is commonly exudation beneath the horny cuticle, giving rise to small vesicles, or *E. vesiculosum*, the typical ecze^ma of Willan, and in a pyogenic constitution these vesicles may be converted into pustules, constituting *E. pustulosum* or *impetiginosum*. When the exudation from the surface is so excessive as to sweep away the cuticle completely, and pour forth from the inflamed skin like a veritable catharrh, the form is termed *E. ichoransum* or *mutidans*, and, from the depth of colour of the vascular base which supplies the exudation, *E. rubrum*. When the exuded secretion is dry on the inflamed surface in the form of crusts, the case is one of *E. crustaceum*, and is well illustrated by the *crusta lactea* of children. When, in consequence of thickening of the affected integument consequent on interstitial exudation, the cuticle is produced in excessive quantity, and continues to desquamate, the ecze^ma is termed *hyperamiosum*, and is the psoriasis of Willan and Bateman. In a more advanced degree of thickening, accompanied with induration, and in chronic stages of the disease, the skin is apt to crack and break,

constituting *E. fissum*, the cracks and clefts being termed *rhagades*. Such a form is not uncommon in the palm of the hand, and constitutes one of the varieties of *porus palmaris*. When, from any cause, a state of permanent hyperæmia is maintained in a part, such as the lower extremities, where it is likewise associated with obstructed venous circulation, the whole of the fibrous and epidermic tissues are apt to become hypertrophied, giving rise to *E. hypertrophicum*.

Besides these, the varieties of ecze^ma due to the predominance of a particular symptom, we recognise dry ecze^ma or *E. siccum*, and moist ecze^ma or *E. humidum*, together with other varieties consequent on locality, such as the scalp, the face, the flexures of the joints, the perineum, and the palms of the hands. We also distinguish, as dependent on severity and duration, acute and chronic ecze^ma, and on period of life, *E. infantile*. Ecze^ma must be considered as one of the most pruriginous of the affections of the skin, hence its Greek names *πρωα* and *πρωϊσσις*, the former being applied to its more acute, and the latter to its chronic form. Itching is most severe in the dry forms of the disease, such as the erythematous, the papulous, and the desquamating kinds, and is relieved by the exudative process, whether occurring normally or produced artificially by the action of the nix or envelopment. In the moist forms the suffering assumes the character of pain, tingling, shooting, and aching, the pain being sometimes so severe as to be suggestive of the term *E. neuroticum*.

Ecze^ma being an inflammation of the surface-membrane of the exterior of the body, is not unfrequently associated with a similar inflammation of the mucous membrane of the air-passages of the lungs, giving rise to bronchitis; hence the complication of ecze^ma infantile with bronchitis is far from uncommon, and in that respect is frequently derivative, a sudden increase of the cutaneous inflammation relieving the mucous membrane, and vice versa; and this association of bronchitis and ecze^ma is sometimes maintained during the whole lifetime of the individual. Sometimes the eczematous bronchitis subsides into a chronic asthma, and sometimes ecze^ma alternates with hay-asthma. Not unfrequently ecze^ma alternates with gout, rheumatism, or neuralgia, acting as a substitute for those affections and suggesting the commonly received opinion that ecze^ma is a consequence of the gouty diathesis. Another and a common complication of ecze^ma are boils, and, in weakly constitutions lymphadenomatous tumours are met with in the axillæ, and sometimes in the eczematous portions of the skin. The complication of ecze^ma with hæmorrhoids and varicose veins of the lower limbs is a well-recognised fact; in the latter instance the dilated and obstructed veins being not only the exciting cause of the ecze^ma, but leading to hypertrophies (enlargement of the integument and cellular structures of the limb—to a state that may fairly be compared with elephantiasis Arabum).

COURSE, TERMINATIONS, AND PROGNOSIS.—The prognosis of ecze^ma will be mainly influenced by the cause of the disease and the constitution of the patient; and, although constantly teasing and generally tedious, it has a

natural tendency to cure, and very rarely imperils life. It is chiefly obnoxious through its itching, which is sometimes so great as to produce violent excitement of the nervous system; and prolonged nervous irritation increases the exhaustion of the sufferer. Where the health of the patient is in other respects fairly good the prognosis will be favourable; but where exhaustion of power prevails, where assimilation is seriously disturbed, and where much irritability of the nervous system exists, the prognosis must be correspondingly unfavourable. Thus eczema infantile, even when extensive, is easy of cure if the constitution of the child be moderately good; the same may be said of the eczema which depends on vaccination, dentition, and growth. The eczema of puerperal patients yields without difficulty to a tonic and nutritive regimen. The eczema which is substitutive of dyspepsia, gout, rheumatism, or neuralgia, is especially influenced by the vitality of the constitution, and so also is that which is due to exhausted nerve-power. The neglected eczema of infancy and childhood may be prolonged for a lifetime, and eczema is not unfrequently one of the indications of broken health, which may alternate with other manifestations of disorder of internal organs, or may be associated with or follow disease of the kidneys, and so prove fatal. Eczema must, therefore, be regarded as a subjective rather than an objective disease, and, although troublesome and tedious, is generally curable. It may annoy the patient for many months or years, recurring with fresh force from time to time, changing with the seasons, and as a complication of other diseases, contributing secondarily to the destruction of life.

TREATMENT.—The treatment of eczema must be *constitutional* as well as *local*, in a very few instances of chronic eczema, when all participation with the original cause has ceased, local treatment alone may be sufficient, but such cases are exceptional. Constitutionally it will be needful to promote and regulate the functions of digestion and assimilation, and restore the powers of the system; but as eczema always implies a want of vital power, a conservative treatment must be maintained throughout. Our best regulators of the digestive functions are saline purgatives with bitter infusions, quinine and iron; sometimes nitro-muriatic acid with a bitter infusion, and a mild aperient pill. When these have effected their purpose, we may have recourse to more decided tonics, such as the citrate of quinine and iron, strychnine, cinchona with sulphuric acid; or when assimilative debility prevails, to the citrates of potash and ammonia. Where there is much nervous irritability the bromides of potassium and ammonium are serviceable; and in the gouty diathesis moderate doses of blue pill, colchicum, and diuretics.

It is not until these remedies have performed their share of duty that we should call into use the valuable aid of arsenic, and then arsenic, as a nerve-tonic and an assimilative tonic, may be said to be specific. To effect these purposes it should be given in small doses, e.g. two to four minims of liquor arsenicalis or the hydrochloric solution, in combination with wine of iron or

tineture of cinchona. In some instances the perchloride of mercury with bark has also proved advantageous. Alkalies, as a rule, are objectionable, and if found necessary for a while, should be discontinued as soon as they produce a debilitating influence on the vital powers. In some few instances, where nervous irritability is the prevailing diathesis arsenic may be adopted from the beginning of the treatment, and infants in general require no preparation for its use.

The *local* treatment of eczema should be *alliative* in the acute forms and stages of the affection, and *stimulant* in its chronic forms. First amongst the soothing remedies is the benzoated oxide of zinc ointment; whilst the stimulants are represented by the mercurial ointments, alkaline ointments and tar. The oxide of zinc ointment is especially intended to form a thin coating of protection to the inflamed skin, and therefore, where it cannot be secured by a bandage will require to be repeated several times a day, for a like reason, and to prevent the removal of the artificial covering so produced, washing of the diseased skin should be carefully prohibited.

In the earliest stages of the eruption great comfort may be afforded by dusting the eruption with starch powder, or starch powder with the oxide of zinc, or simply with fuller's earth; and zinc powder suspended in lime water forms a very useful lotion for protecting the eruption from the atmosphere at all stages of its progress. This latter application is also serviceable in relieving the distressing pruritus which always accompanies eczema. However, the most important of the remedies for the relief of itching are the preparations of tar, and especially a tar lotion composed of soft soap, tar, and alcohol, more or less diluted, and sometimes combined with hydrocyanic acid.

Where eczema is accompanied with much infiltration and oedema of the integument, especially occurring in the extremities, a process of sweating the limb by means of water-dressing and a waterproof envelope has been adopted with considerable success. And a modification of this treatment by the use of the envelope at night, and the zinc ointment during the day, may be very conveniently adopted in cases where the patient is unable to keep his bed, and is called upon to pursue his daily avocations in life during the continuance of the treatment.

In very chronic cases, again, where there is considerable hardness and condensation of the skin, it may be necessary to apply a blister over the part, and afterwards dress the blistered surface with zinc ointment; or, a milder course consists in the application of a strong alkaline solution or soap. ERASMUS WILKINSON

ECZEMA Marginatum. See TINKA.

EFFUSION (*r. out, and fundo, I pour*).—The escape of a fluid from its natural channel or cavity into the substance of organs or the cellular tissue, or from free surfaces. An example, may be mentioned dropsy in its various forms, and effusions resulting from inflammation.

EGYPT, UPPER.—A very dry, toxic

winter-climate. Mean winter temperature, 62°. Season, (October to March. See CLIMATE, Treatment of Disease by.

ELECTRICITY.—The purposes for which electricity is employed in medicine are various. It is used as a stimulant to excite muscular and nervous tissue which is the seat of paralysis or pain, and as a stimulant to the tissues generally; its chemical action may be employed for dissolving tissues and coagulating blood within aneurismal sacs, and its thermal effects are employed in surgery for heating cauteries. Electricity is used in its three forms of (1) *Franklinic, Static, or Frictional electricity*; (2) *Faradism* (i.e. electricity generated by induction, whether voltaic or magnetic), and (3) *Galvanism* or *Voltaism*, which owes its existence to chemical action.

APPARATUS.—*Franklinic electricity*, which is generated by the friction of glass discs or cylinders, and which was formerly much in vogue, has now become nearly obsolete in therapeutics, and need not detain us in an article like the present.

Faradic batteries should consist of (1) a coil of insulated copper wire, the ends of which are in connection with the plates of a galvanic cell. This is called the *primary coil* and contains a bundle of soft iron wire in its interior. 2. A second coil of insulated copper wire made of finer wire and containing a greater number of spirals than the primary, which is made to slide over the primary. This is called the *secondary coil*. 3. An *interrupter*, capable of interrupting the current automatically and with great rapidity by means of the constantly recurring magnetic action of the bundle of iron wires in the interior of the primary coil. These batteries should have means of graduating the intensity of the current of either coil and of including the patient in the circuit of either coil without altering the connections of the conducting wires. Sometimes the galvanic element is replaced by a large magnet, as in the well-known rotating magneto-induction apparatus.

Galvanic batteries when used for therapeutic or electrolytic purposes should be composed of (1) a large number of small cells of low electromotive force, and as constant in their action as possible. The cells known as the 'Leclanche' are the best. (2) Means of including in the circuit any number of cells at will, so that thereby the intensity of the current may be regulated. (3) Means of opening or closing the circuit at will and of reversing the direction of the current without altering the position of the current-carriers (rheophores) on the patient's body. This is effected by means of a simple contrivance known as a *key and commutator*.

Batteries which are required for heating wires and cauteries must be composed of cells of high electromotive force and as large as is practically possible. The number of cells or elements is of less importance than their size. It is not unusual to have, for this purpose, Groves' or Bunsen's cells capable of containing a pint of liquid each.

The essential and distinctive differences of the two forms of current (galvanic and faradic) are the following:—

The Galvanic Current is (1) *continuously evolved* (hence it is spoken of frequently as the 'continuous current'). (2) It *flows always in the same direction*, i.e. from the positive pole (which is in connection with the copper or receiving plate) to the negative pole (which is in connection with the zinc or generating plate). This fact must be constantly borne in mind, because the action of the two poles is markedly different, and it has been asserted (on very doubtful evidence, however) that the direction of the current in the body, whether towards the nerve-centres or towards the periphery, has an important effect upon the physiological and therapeutical results. (3) It has well-marked *chemical and thermal effects*. This action is most marked at the negative pole, with which if a moderately intense current be used, heat, redness, inflammation, and even sloughing of the skin may be readily produced. It is, therefore, always necessary to frequently change the position of the negative pole on the body. (4) It has *electrolytic effects*. When a galvanic current is passed through a conducting compound liquid, decomposition of the liquid results, oxygen (if water only be used) and acids (if saline solutions be used) being evolved at the positive pole, while hydrogen or alkalis, as the case may be, are evolved at the negative pole. Since the human body consists of a mass of cells which contain and are bathed in saline fluids, many of the phenomena observed on passing galvanic currents through the human body, or any part of it, are probably due to this electrolytic action. Faraday called the positive pole the *anode*, and the negative pole the *cathode*, and these terms are frequently employed.

Induced Current.—With regard to the induced current, the following points must be remembered (1) It is *momentary in duration*. (2) Its *direction is constantly changing*, so that in using it it is less necessary to distinguish between the poles. (3) Its *chemical, thermal, and electrolytic effects are nil*. (4) It has much greater 'tension' than the galvanic current, that is, it overcomes the resistance of the body with far greater ease. (5) It *causes the contraction of healthy muscle far more readily than the galvanic current*. Muscular contractions only occur at the moment of making or breaking a current, and it is mainly to the rapid interruptions of the induced current that its high stimulating power is due. The current of the secondary coil has greater tension, more penetrating power, and greater stimulating power than the current of the primary coil or 'extra-current.' This is due to its being composed of finer wire and having a greater number of turns.

The stimulating effects of the galvanic current which cause muscular contraction, occur only at the moment of making or breaking the current and not during its continuance, and the stimulating effect of the two poles is different, as may be demonstrated by the 'Polar method of investigation,' instituted by Brenner, of St. Petersburg. If one rheophore be placed on an indifferent part of the body, as the back, and the other be placed over a nerve-trunk or muscle, we are able by means of the commutator and key to study the action of either pole on nerves and muscles during the making and

breaking of the current. With weak currents it is found that contraction ensues only when the stimulating rheophore is negative (cathode), and only on closing the circuit. This is called *Cathodal Closure Contraction (C.C.C.)* If the strength of the current be slightly increased we get contraction also when the stimulating rheophore is positive (anode), and the circuit is opened (A.O.C.). Next follows *Anodal Closure Contraction (A.C.C.)*, but *Cathodal Opening Contractions (C.O.C.)* never occur in healthy muscles with any currents short of those of unbearable intensity.

The galvanic current, unlike the induced current, affects the nerves of special sense. If applied in the neighbourhood of the eyes, flushes of light are seen, and blindness has resulted in one case from the incautious application of strong currents to the face. The gustatory nerve is affected in a similar way, and the 'galvanic taste' is perceived when the rheophores are placed on the cheek. The taste is acid with the positive, but metallic and coppery with the negative pole. If the rheophores are held to the ear rumbling noises are produced, and it is said that stimulation of the olfactory nerve will give rise to a peculiar smell.

Onimus has pointed out a further distinction between the induced and the galvanic current. 'An induced current,' he says, 'only acts during the infinitely short time of its passage, after which everything returns to order . . . It can never be anything else but a series of slight excitations. With constant currents real excitement is determined only at the times of making and breaking . . . It is during the silent period, however, that the principal action of the continuous current makes itself felt.'

It is certain that the rapid interruptions of the induced current and the strong muscular contractions caused thereby, are capable, if the current be moderately strong, of rapidly and completely exhausting the irritability of a muscle, and, if this fact be not constantly borne in mind, harm instead of good will result from the application of faradism. The galvanic current, on the contrary, possesses remarkable refreshing effects, a fact which has been demonstrated by Heidenhain on frogs, and by the writer on the human subject. It is found that a man can sustain a weight at arm's length far longer than he otherwise could, if a galvanic current be passed through the nerves of the limb. The feeling of fatigue can be removed by the application of the current, and the force of muscular contraction is increased thereby. These facts have important therapeutic bearings.

Modes of Application.—To apply electricity we need to have conducting wires and rheophores or current-carriers attached to the battery. The best conductors are made of ordinary telegraph wire, which should be as thick as is compatible with pliability. Telegraph wire is not damaged by moisture and can be readily connected to all forms of batteries and rheophores, and is therefore economical as well as convenient. Rheophores vary much in design. They should all have insulating handles, and the junction between the conductor and rheophore should be about the middle of its length, so that both conductors may

be held in one hand without risk of the metallic junctions coming in contact. The most generally useful rheophore is the sponge-holder. An excellent sponge-holder, which retains the sponge with absolute firmness, has been made for the writer by Messrs. Weiss, from a design by Kidder of New York. Rheophores should be of different sizes from a sponge as big as half-a-crown to the pointed extremity of an olive-shaped conductor. They should be made of metal and not carbon because the latter is too brittle. They may be obtained in the form of discs, balls, points, and of endless design for reaching particular organs and regions, as the eye, ear, larynx, bladder, rectum, and uterus. They are usually covered with wash-leather, and used moist. A wire brush is useful for influencing the skin. The dry hand of the operator, who allows the current to pass through his own body to that of the patient, may be used for the same purpose. It is often convenient to fix one rheophore to the patient's body, which may be accomplished by placing an ordinary sponge on the surface of the body, laying thereupon the naked end of the conducting wire, and securing the whole with one turn of a bandage. If we wish to influence the surface only, we may use one rheophore dry, but if we wish to affect deeper-lying structures we must overcome the resistance of the epidermis by thoroughly moistening it with hot salt-and-water. We may use one rheophore dry, and one moist; or we may use as a rheophore a porcelain or gutta-percha vessel containing water, into which the limb is placed.

There are two methods of applying electricity, known as *general electrization* and *localized electrization*. By the former method we pass the current through the entire body or great part of it, it has been employed for many diseases, but its utility is doubtful. By the latter method, which we owe to Duchenne, we seek to influence special nerves, muscles or organs, and to limit the action of the current strictly to these parts. If we wish to influence a muscle we may do so either by applying the rheophores directly over the fibres of a muscle (both the rheophores being held in one hand and 'promenaded' over the whole surface of the muscle). This is the direct method, and is the method advocated by Duchenne. Or, instead of trying to influence the muscle itself, we may stimulate the nerve supplying it, and so cause the muscle to contract. This is the indirect method, advocated by Ziemssen. It is effected by using two rheophores of different sizes. A large rheophore is affixed to an indifferent part of the body, while with a small pointed rheophore an endeavour is made to touch the exact point where the nerve we seek to influence is most superficial. Neither of these methods is to be exclusively adhered to. Certain deep-lying muscles, such as the diaphragm and the supinator brevis, are only capable of indirect stimulation. It will be found also that, in certain diseased conditions, muscles will not respond to stimulation through the nerves, but only to the direct application of the current. When we wish to use the refreshing effects of the current, as in cases of paralysis which are on the road to recovery, or in cases of

fatigued muscles, &c., it is advisable to combine the application of the galvanic current with a rhythmical exercise of the affected muscles. Benedikt lays it down as a rule that the *locus morbi*, be it brain, spinal cord, nerve, or muscle, should always be included between the rheophores.

DIAGNOSTIC AND THERAPEUTICAL USES.—

1. **Diagnostic Uses of Electricity.**—For purposes of diagnosis, electricity is of undoubted service, since by its means we are often enabled to distinguish between paralysis due to central lesion and paralysis due to peripheral lesion. We are accustomed to speak of a paralysis as 'central' so long as that portion of a nerve-centre is sound from which the nerves supplying the paralysed muscles take origin. Thus in cases of damage to one corpus striatum, the spinal cord and the greater part of the brain being healthy, we speak of the case as one of central paralysis. In cases, too, of paraplegia from local injury, the cord below the injury being healthy (notwithstanding that all mental control is cut off) we speak of the paralysis as central. In such cases of central paralysis we find (a) that reflex stimulation of the muscles is possible, (b) that the muscles undergo but little wasting and (c) that the irritability of the muscles to faradism is scarcely diminished. We speak of paralysis as due to a peripheral lesion whenever the paralysed muscles are cut off from communication with their nerve-centres, or directly communicate with centres whose physiological activity has been destroyed by disease. In such cases we find (a) that reflex stimulation of the paralysed muscles is no longer possible, (b) that the paralysed muscles waste with remarkable rapidity, and (c) that the irritability of the muscles to faradism is rapidly diminished, and is generally ultimately destroyed. To establish the fact of diminished irritability to faradism is generally not difficult and in cases of paralysis affecting one side of the body only it is done by comparing the paralysed muscles with their healthy fellows. We must take care that the current does not vary in intensity, and that it passes through exactly similar lengths of the body for the stimulation of both sets of muscles. It will be found convenient to fasten one rheophore to the middle line of the body (a big sponge tied to the back of the neck answers well), and then when the patient's limbs are arranged exactly symmetrically, test the healthy muscles first with a small or pointed rheophore and determine the current of least intensity which will cause contraction. Then the rheophore is to be applied to exactly the same spot on the opposite limb, and, if contraction follows as readily as on the healthy side, we know that there is no diminution of irritability. If, however, contraction do not follow, we increase the strength of current, and so determine to what extent the irritability is diminished, and whether or no it is completely extinguished. We should add that in cases of peripheral paralysis the diminution and extinction of irritability does not supervene immediately on the occurrence of the paralyzing lesion, but only after the lapse of a week or ten days. In cases of paraplegia or other cases in which paralysis affects both sides of the body it is, of course, impossible to compare a para-

lysed muscle with its healthy fellow, and in such cases we can only judge of the amount of irritability by experience and mental comparison with previous cases. It is found, in cases of peripheral paralysis, that after complete extinction of faradic irritability the muscles will respond to a slowly interrupted galvanic current, and that not unfrequently the irritability of the muscles to galvanism is greater on the paralysed than on the sound side of the body. It is said by some German writers that not merely quantitative but qualitative changes take place in the irritability of these muscles and that the Anodal Closure Contraction (A.C.C.) soon becomes very marked, and equals or even surpasses in force the Cathodal Closure Contraction (C.C.C.); and further that the Cathodal Opening Contraction soon becomes more marked than the Anodal Opening Contraction. These reactions, which are supposed to depend upon degenerative changes in the muscle, have been spoken of as the *degenerative reactions*. These quantitative and qualitative changes in irritability are found (1) in some forms of paraplegia due to degenerative changes in the cord, (2) in so-called spinal paralysis both of infants and adults, (3) in traumatic paralysis due to injury of the nerve-trunks, (4) in rheumatic paralysis, that is, paralysis due to 'rheumatic' thickenings of the neurilemma, and (5) in lead-paralysis.

In ordinary hemiplegia the irritability of the muscles remains, as a rule, unchanged. In some cases, however, the irritability is increased in the early stages, and occasionally after the paralysis has lasted some time we find slight diminution of irritability. In the disease known as Progressive Muscular Atrophy, the irritability of the wasted muscles to faradism remains undiminished to the end.

2 Therapeutical Uses of Electricity.—

a. *In Paralysis.*—The treatment of paralysis by means of electricity must be conducted rationally and with discrimination. By means of electricity we may attempt to remove the cause of the paralysis by influencing the nutrition of the parts where such cause is situated, by acting on the sympathetic nerve-branches supplying the blood-vessels of the part. Thus it is asserted that the absorption of a clot in the brain may be hastened, and that the nutrition of a damaged brain may be improved, by acting upon the cervical sympathetic nerve. To influence the cervical sympathetic we place one rheophore over the superior cervical ganglion (which may be reached by pressing inwardly behind the angle of the jaw), and the other on the back, over the first and second cervical vertebrae. The use of such a proceeding is more than doubtful, and in case of any improvement occurring it would be impossible to know to what such improvement ought to be attributed, since the passage of a current across the upper part of the neck must influence many important nerves besides the sympathetic. On the whole, we think that galvanisation of the sympathetic is not to be advised in the early stages of paralysis. Galvanisation of the sympathetic has been employed in chronic degenerative changes in the brain or cord, but with very doubtful success.

The localised application of the electric cur-

rent to the paralysed muscles is of unlimited service, and in employing it we should bear in mind the following rules. 1. As to the object of our treatment we should remember the words of Sir T. Watson, 'That our aim is to preserve the muscular part of the locomotive apparatus in a state of health and readiness, until period-venture that portion of the brain from which volition proceeds having recovered its function, or the road by which its messages travel having been repaired, the influence of the will shall again reach and reanimate the palsied limbs.' 2. Always to employ that form of current to which the muscles most readily respond. Thus if the muscles act readily to faradism, then faradism is to be used. In some cases of peripheral palsy we find that contraction follows only on the application of a very strong galvanic current, very slowly interrupted, and accordingly a slowly interrupted galvanic current must be used. As the case improves we shall find that a weaker current produces similar results, and that the muscle contracts with moderately rapid interruptions. And so will improvement gradually take place in favourable cases till faradic irritability and lastly voluntary power are restored. 3. Always to employ the weakest currents which will cause muscular contraction, and never to run the risk of exhausting a muscle by causing a too prolonged contraction. Each muscle should be taken in turn, and be made to contract two or three times in succession, and having gone over the whole of the paralysed muscles seriatim the process may be repeated. An application of this kind every other day is usually sufficient. 4. If the paralysis to the will remain absolute, and if the contractility of the muscles be perfect, we do no good by persevering with electrical treatment. This condition is often met with in hemiplegia. The patient is absolutely helpless on one side, although the paralysed muscles are in no degree wasted, and their irritability remains normal. 5. If the paralysis to the will remain absolute, and if the irritability of the muscles be diminished, then electricity is useful, in so far as it helps to improve the nutrition of the muscles and restore their normal degree of irritability. The normal degree of irritability and nutrition being restored (the paralysis to the will remaining absolute) electrical treatment may be discontinued. 6. If the irritability to both forms of current has completely disappeared, we are not justified in persevering too long, nor in holding out delusive hopes to the patient. Nevertheless, treatment should not be abandoned without a patient trial. [For the treatment of special forms of paralysis by electricity, the reader is referred to the appropriate sections of this work.]

6. *In Painful Affections*.—The power of electricity to relieve pain is very great. The relief is usually temporary, but in many cases is permanent. Electricity may act by serving to divert the mind from troubles real or fancied, or its counter-irritating effects may serve the same purpose as other counter-irritants whose power to relieve pain is well recognised. Occasionally electricity will give relief when every known remedy has failed, and in such cases we must suppose that it acts by bringing about some change in the

nerves themselves by its specific action on nervous tissue. All three forms of electricity are employed for the relief of pain, but the galvanic current will be found the most generally applicable. Some writers insist that the anode (positive pole) shall be applied to the painful spot. Strong faradisation serves in some cases to give relief. The effects of galvanism should be tried in every case of neuralgia, but it is not capable of relieving all cases, and disappointment is not unfrequent. Where muscular movements increase the neuralgic pains, a rhythmical exercise of the affected muscles should be conjoined with the galvanism. Headache of all kinds not unfrequently yields to electricity, lumbago, sciatica, and those painful muscular conditions which we call 'rheumatic' are quickly relieved by it. Tinnitus aurium will sometimes yield to the galvanic current when all other remedies have failed.

7. *In Spasmodic Diseases*.—In the treatment of spasmodic diseases, electricity is of limited utility. Some forms of tremor are relieved by it. Several aggravated cases of writer's cramp have yielded to it when all other remedies have failed, and a few cases of chronic torticollis have received undoubted benefit by its judicious application. Tonic spasm of internal organs, such as the bowel and bladder, has been relieved by the galvanic current.

8. *In other diseases*.—In addition to the treatment of diseases of a purely nervous character, electricity has been employed as a remedial agent in diseases whose origin is not so obviously connected with the nervous system. It has relieved the paroxysms of angina pectoris, and the burning pains which accompany herpes zoster. It has been employed in the treatment of many obstinate skin-diseases by American physicians, and Dr. Chasle has recorded a case in which the dilated vessels in a case of acne rosacea were made to contract by faradisation. Rheumatic gout is said to have been benefited by a 'central' application of galvanism (one pole to the nucha, and the other to the epigastrium). The flow of urine in diabetes has been stated to be diminished by a similar process, and the symptoms of exophthalmic goitre have (it is said) been diminished by galvanisation of the cervical sympathetic. There is in fact scarcely a disease, from epilepsy to chilblains, in which it has not been alleged that electricity has been of use. In obstetric medicine for the arrest of post-partum hemorrhage, faradisation is now one of the recognised means to be employed; and it has been of more doubtful service for the rectification of displacements of the uterus. Ovarian pain and tenderness have been relieved by the galvanic current, and amenorrhœa has often yielded to electricity.

9. *Galvano-cautery and Galvano-puncture*.—The chemical and thermal effects of galvanism are largely employed both in surgery and medicine. Its thermal effect has been used for the heating of cauteries; and cauteries so heated have very obvious advantages over all other forms. The chemical effect of the negative pole has been used as a caustic for the destruction of tissues, and tumours of considerable size, say, it is said, been 'dispersed' by this means.

Galvano-puncture has been used in the treatment of hydatid cysts of the liver, but it is at least doubtful whether simple puncture is not quite as serviceable. Galvano-puncture seems likely to take a recognised position among the means at our disposal for the treatment of aortic aneurisms. Several cases have been recorded in which improvement has followed this method of treatment, and it seems possible that the operation may be accomplished without danger and almost without discomfort to the patient. The current employed should be generated by a number of small cells of low electromotive power (Smee's cells as modified by Foreaux seem the best). Each pole should terminate in a fine steel needle, carefully insulated except at the point. Both these needles should be passed completely into the aneurismal sac, care being taken that the points of the needles are free in the sac, and that they do not touch, but are separated by an interval of an inch or inch and a half. When the current passes, the whole of its effect will be exerted on the blood within the sac, and, owing to the insulation of the needles, the coverings of the sac will receive no damage. The effect of the current is to cause a firm coagulum to form round the positive pole, while the liberation of gas at the negative pole causes there a frothy soft coagulum. As a rule the gas generated is swept onwards by the blood-current and causes no trouble, but occasionally distension of the sac has resulted. The clot formed at the positive pole seems to act as a foreign body, and further coagulation may take place around it, until complete consolidation of the aneurism has resulted. It will be found that a current from ten or twelve cells can be borne for an hour or more, and that no chloroform will be needed for the operation. When the needles are withdrawn the orifices must be closed by collodion. A repetition of the operation is generally necessary, and may be performed at suitable intervals.

G. V. POORE.

ELEPHANTIASIS ARABUM (*إلحاف*, an elephant).—**SYNON.**: Fr. *Elephantiasis*; Ger. *Elephantiasis*.

DEFINITION.—A non-contagious disease, characterised by recurrence of febrile paroxysms, attended by inflammation and progressive hypertrophy of the integument and areolar tissue, chiefly of the extremities and genital organs, and occasionally by swelling of the lymphatic glands, enlargement and dilatation of the lymphatics, and in some cases by the co-existence of chyluria, and the presence in the blood of certain nematode hæmatozoa, together with various symptoms indicative of a morbid or depraved state of nutrition.

ETIOLOGY.—Elephantiasis is endemic in India, the Malayan peninsula, China, Egypt, Arabia, the West Indies, and parts of America, chiefly in localities within the influence of the sea air; and it occurs sporadically all over the globe, excepting, perhaps, in the extreme north and south. Certain conditions of soil and climate, such as humidity, heat, malarious influences, and proximity to the sea-coast, seem to be concerned in producing the disease and influencing its development. Removal from the territorial endemic area

checks the disease, whilst return there reproduces it. Elephantiasis affects both sexes, and persons of all ages and conditions of life. No race is exempt, but it is much more frequent in dark than in fair races, and more men suffer from it than women. It occurs at all ages, but is most common in adult and middle life, comparatively rarely beginning in young children or in the aged. Elephantiasis is doubtfully hereditary; but Richards found that of 236 persons, 73 per cent. had one or both parents affected. Various causes are assigned for the disease. Air, water, food, and, as it is common near the sea-coast, eating fish have been frequently credited with producing it. The presence or vicinity of certain forms of vegetation and the geological formation of the soil, have also been regarded as predisposing and determining causes. Climate and locality, combined with bad living, are doubtless the real predisposing causes; and it is probable that, as Dr T. Lewis has suggested, it may be found to be intimately associated with the presence in the blood of certain parasites. No race is exempt from the disease, but, whatever may be the explanation, the white suffer less than the dark races. It does occur occasionally, though very rarely, in the pure European in India, but more frequently in those of mixed descent; it will generally be found that where it occurs in persons of apparently European parentage, there is a mixture, however slight, of dark blood.

ANATOMICAL CHARACTERS.—The hypertrophy of elephantiasis in most cases appears to be simply an increase in the natural elements of the part, the blood-vessels and lymphatics sharing in the growth. In other cases the lymphatics and lymph-spaces are most concerned, giving rise to a condition that has been described as *ædæd elephantiasis*, in which the appearance is presented of a soft and fluctuating swelling, which when punctured gives issue to a white or pinkish fluid, very closely resembling chyle. The lymphatic glands also share in the enlargement. In other respects the progress of this is like that of the ordinary form of the disease.

The *Filaria sanguinis-hominis* is sometimes found in great numbers in the blood of persons suffering from elephantiasis. See *FILARIA SANGUINIS-HOMINIS*.

SYMPTOMS.—The ordinary form in which elephantiasis presents itself is hypertrophy of the integument and areolar tissue of some part of the trunk or limbs, and notably of the legs and genital organs. The skin becomes enormously thickened by hypertrophy of all the fibrous elements of its structure, attended by the deposit of a quantity of albuminous fluid in the cells of the areolar tissue. The papillæ are prominent and much increased in size. The integument is formed into hard masses or folds, with a ragged condition of the surface, not unlike the appearance of an elephant's leg. The feet and toes are sometimes almost hidden, and the scrotum or labia form enormous outgrowths. The scrotum often attains great weight, and may be accompanied by large hydroceles. Scrotal tumours have been removed weighing upwards of 100 lbs.

The onset of elephantiasis is frequently violent and attended with great suffering. There is

high fever; intense pain in the lumbar region, groin, spermatic cords, and testes, which become swollen; while acute hydroceles form. These symptoms are often attended with sympathetic vomiting, nausea, and rapid erythematous swelling of the external parts; and, if the extremities be attacked, the swelling may be tense and painful, accompanied by much effusion into the areolar tissue. The surface of the integuments is much inflamed, and sometimes discharges a serous ichor or chylelike fluid, according to the extent to which the lymphatics are engaged in the particular case. The great tension and swelling of the spermatic cords are apt to dilate the abdominal rings so widely, that after recovery the patient may suffer from hernia.

In some cases of elephantiasis the integuments are also the seat of a dilated and turgid condition of the lymphatic vessels, which during the periods of vascular excitement, when the febrile attacks occur, give way and discharge a chylelike fluid; in other cases the surface temporarily assumes a herpetic condition, which weeps an acrid and offensive serous exudation.

Elephantiasis not unfrequently occurs without much or any obvious injury to or disturbance of the general health during the intervals between the febrile attacks, which in some cases are few and slight. The appetite, spirits, and strength are good, the functions are all normally performed, and the only inconvenience is that due to the size and weight of the outgrowth. On the other hand, it is frequently quite the reverse, the rapidly recurring febrile attacks pain, exhaustion, suffering, and visceral complications induce a state of cachexia and debility sometimes so serious as to render even surgical interference impracticable. Withal, hepatic and splenic enlargements do not as a rule result from the persistence of the elephantoid fever alone, though not unfrequently, as a more direct result of malarious poisoning, they seriously complicate the evils of the sufferer's condition. Albuminuria, as well as chyluria, is occasionally present.

In some cases, after the outgrowth has attained a certain bulk, it ceases to grow altogether, or increases slowly and insidiously without febrile disturbance, and in such cases the general health remains good. But there is generally a tendency to recurrence of the fever once or twice a month, when the parts affected become tense, hot, painful, and swollen and often discharge a serous or lymph-like fluid, which may be acrid and offensive. Some tumours, on the other hand, are very slightly, if at all so affected, and remain perfectly dry. In all cases, however, some growth goes on, and even when, as occasionally happens, fever has ceased to recur, there may be a gradual, but slow and painless, increase of the hypertrophy. The greatest variety and uncertainty obtains in the duration and progress of the growth; sometimes it is very rapid, at other times it is slow, with intermissions of activity and indolence of development.

The disease elsewhere than in the genitals, unless it be accompanied by exhaustion and debility, causes no failure in the generative powers in either sex. Women may have a tendency to miscarry when suffering from elephantiasis.

Course, Duration, and Terminations.—Ac-

cording to Richards the average duration of the disease, as deduced from the observation of 634 cases, was 11½ years; and he notes that the earliest age was nine years, whilst the latest at which he observed it was eighty years. It appears from this that the disease has little influence in shortening life.

PATHOLOGY.—The outgrowths in elephantiasis are the local expressions of a constitutional disease, and are not to be regarded merely from their local point of interest. They are the result of certain climatic influences whose exact nature is not at present determined; though, considering the geographical range of the area where the disease is endemic, it seems probable that, whatever other cause may be at work, the so-called malarious influences play an important part in its production.

The recent researches of Dr. T. Lewis into the pathology of chyluria in India, and his discovery of certain hæmatozoa in the blood of those affected with that disease, coupled with the fact that the subjects of chyluria and hæmatozoa are also frequently, if not always, affected by elephantiasis with its febrile paroxysms, hypertrophied integument and lymphatic disturbance, are very suggestive of a community of origin of these morbid conditions.

TREATMENT.—Little has yet been done by constitutional treatment in cases of elephantiasis. Remedies useful during the febrile paroxysms have little power in preventing recurrence or in checking the disease. Iodine, combined with quinine, arsenic and iron, has been found useful to a certain extent. During the febrile state salines, diaphoretics, and such remedies as are needed during the pyrexial state of malarious fevers, are indicated. Opium may be necessary to relieve the intense pain which often accompanies the onset of the stage of excitement. When the febrile stage has passed, quinine is useful, which, if anæmia exist, should be combined with iron. The local application of iodine in such forms as the iodide of lead or the biniodide of mercury has been thought useful; but as this is generally combined with pressure in the recumbent posture, the benefit is probably due to the latter. Such measures, along with improved hygienic conditions, may no doubt control the progress of the disease and relieve suffering. No remedy, however, is so potent as change of climate, by removal from the endemic site of the disease. This, if effected in the earliest stages, may completely arrest the disease, and perhaps even disperse any incipient structural change. This has been observed in the rare cases in which elephantiasis occurs in Europeans, who on returning to Europe, have after a time lost the disease, and almost or entirely, any hypertrophic changes that may have occurred. Natives of India improve if they leave the endemic area during the early stages, and go and reside in other and drier localities. However, when the hypertrophy is advanced, the paroxysms of fever are still liable to recur, even when the climate is changed, though with less violence.

Surgical treatment, where the hypertrophy is advanced, is often most successful in relieving the sufferer, not only of the local trouble, but also of the fever. Tumours of the genital organs,

sometimes of enormous size, are now removed with complete success and comparatively small mortality. Before commencing the operation, especially in the case of a large scrotal tumour, it is well to drain it of blood by placing the patient on his back, and elevating the tumour on the abdomen for an hour or so, during which time pressure by a bandage (a modification of Eschmarch's) may be tried, and cold (ice) may be applied. During the operation the application of a whipcord ligature drawn tightly round the neck of the tumour also prevents loss of blood.

The removal of a scrotal tumour is effected by incisions along the course of the cords and the dorsum penis. The cords, testicles, and penis are turned out by a few touches of the knife, and then reflected and held up on the abdomen, while the mass of the tumour is rapidly swept away by a few bold incisions in the perineum. The numerous venous and arterial bleeding points should then be arrested and the wound dressed with oiled lint covered with antiseptic dressing. No attempt should be made to preserve flaps of integument either for the penis or testes. It is unnecessary, and almost certain to be followed by recurrence of the disease. The process of cicatrization goes on rapidly, and in from two to four months all is closed in by cicatricial tissue, which gradually perfects itself, and has no liability to become the seat of a return of the disease. If the shock be severe the patient should be left on the table until reaction has thoroughly set in. Of 193 cases of scrotal elephantiasis operated on in the Medical College Hospital in Calcutta, 182 per cent. proved fatal.

JOSEPH FAYRER.

ELSTER in Saxony—Alkaline sulphated waters. See MINERAL WATERS.

EMACIATION (*emacio*, I make lean)—Wasting or loss of flesh. The term is applied both to the process of wasting, and to the condition that results therefrom. See ATROPHY.

EMBOLISM (*εμβολισμός*, a plug)—*ΣΥΝΟΝ.* Fr. *embolie*, Ger. *Embolie*.

DEFINITION—The arrest in the arteries or capillaries of some solid body, which has been carried along in the course of the circulation.

PATHOLOGY.—Emboli usually consist of portions of fibrine derived from thrombi of the veins or heart, or of vegetations detached from the cardiac valves. They may, however, be formed by fragments of tumours which have grown into the blood-vessels, or of other foreign bodies which have obtained entrance into the circulation.

The effects of embolism may be divided into two classes:—First, those which are caused by the arrest of the circulation; and secondly, those which are due to any specially irritating properties of the embolus.

The embolus may, first, be supposed to consist of some indifferent substance not possessing any irritating qualities. The effects which may then be caused by arterial embolism are mainly these:—First, a transient anæmia of the territory

supplied by the blocked artery. This may pass away without leaving any permanent consequences. Secondly, necrosis of this territory. This may be either sudden, in the form of gangrene; or more gradual, in the form of softening or withering. Thirdly the formation of a *hæmorrhagic infarction*, that is, congestion of the territory, followed by extravasation of blood into the tissues, and so the formation of a firm, solid patch of a dark red colour, usually of a wedge shape, with the apex towards the embolus, and the base towards the periphery. In very soft organs, as the brain, the extravasation may break down the tissue and cause the ordinary phenomena of an apoplectic clot. These hæmorrhagic infarctions undergo various subsequent changes. Usually a process of degeneration sets in, the blood-pigment passes through its usual transformations, the patch changes from dark red to tawny and yellow, undergoes molecular disintegration, shrinks away, and ultimately leaves a depressed fibrous patch in which the remains of the altered blood, crystals of hæmatoidin &c., may often be recognised. Sometimes the patch softens down into a purulent fluid, which may become surrounded by a fibrous capsule, and ultimately dry up, or even calcify. When recent these patches are usually surrounded by a halo of congested vessels.

The cause which determines these different results of arterial embolism is, in the main, the anatomical arrangement of the blood-vessels. Supposing the embolus to be lodged in an artery which gives off anastomotic branches between the seat of the embolus and the final capillary distribution, the effect in most cases will be transient anæmia: the collateral channels will enlarge, and the circulation will be again restored. A thrombus will form on the embolus and will extend back to the next arterial branch, and the changes described in the article on thrombosis will take place in it (see THROMBOSIS). If the blocked artery be of large size, and supply important organs, the symptoms of temporary arrest of function of the part supplied by the artery will follow, as transient paralysis, dyspnoea, coldness of the extremities, &c., according to the artery affected. Should, however, the artery be small, and not supply important organs, no symptoms whatever will be caused, and this is the case in the majority of embolisms. Supposing, however, the artery is what Colnheim calls a *terminal* artery, i.e. one which gives off no anastomotic branches between the embolus and the final capillary distribution, and that the capillary anastomosis with other arterial territories is insufficient to supply a collateral circulation, and that the presence of valves prevents the reflux of blood into the territory from the veins, it is manifest that the embolism must completely cut off the blood-supply, and consequently cause necrosis in some form or other of the territory.

The network of anastomosing channels is, however so close in most parts of the body, that in order to produce this effect it is necessary either that the main artery of the part be obstructed, or else that there be multiple embolisms blocking up at the same time several arterial branches, and so stopping the channels of collateral circulation.

The mode in which the hæmorrhagic infarction is produced is still a subject of dispute. According to Cohnheim, whose views until recently were generally accepted, the hæmorrhage is due to a reflux from the veins into the territory supplied by the blocked artery. This first causes congestion, and then extravasation, in consequence of impairment of nutrition of the walls of the blood-vessels, for the integrity of which the circulation of the blood is essential. According, then, to Cohnheim, in order to produce the phenomena of the hæmorrhagic infarction it is necessary that the artery be a terminal one, i.e. one which gives off no anastomotic branches for some distance before its final capillary distribution, and that the veins be not furnished with valves. These conditions are met with in the spleen, the kidney, the brain, certain branches of the pulmonary artery supplying surface lobules, and the central artery of the retina, and on these grounds he accounts for the frequent occurrence of hæmorrhagic infarctions in these organs, though there is no reason to suppose that, with the exception of the lungs, embolism is more frequent in them than in other parts.

The more recent researches of Dr. M. Latten, *Zeitschrift für klinische Medicin*, Vol. I., render, however, these views no longer tenable. He shows by experiments on the kidney, spleen, lung, &c., that if the blocked artery be a strictly terminal one, i.e. one whose area of distribution has no other arterial supply, the phenomena of the hæmorrhagic infarction do not occur, even though the vein have no valves, and under other circumstances that the infarction takes place although the vein has been ligatured, hence the cause of the infarction cannot be venous reflux. Thus if both the renal artery and vein be ligatured, infarction of the kidney takes place, the kidney receiving a sufficient collateral supply of blood from other sources, but if the capsule were first stripped off, and the kidney be left attached only by the renal artery and vein, no infarction took place, though the vein was left pervious. Similar results were obtained in other organs; hence it would seem evident that the congestion and infarction following embolism are produced by an afflux of arterial blood into the territory from collateral channels. Should these be numerous, and should small arteries open directly into the anæmic territory, the circulation will soon be restored, and no infarction will take place, should, however, the communication be imperfect, and only by means of capillaries, a congestion of the territory leading to diapedesis and infarction will result, the *vis a tergo* being insufficient to propel the blood onwards into the veins.

He has also shown that the vessels in which the circulation has been arrested retain their integrity much longer than was supposed by Cohnheim, and that in the kidney long before the vessels suffer necrosis of the epithelium takes place, the nuclei of the cells disappear, their protoplasm coagulates, and they become converted into swollen hyaline masses (*coagulation necrosis*), which have a remarkable tendency to calcification. Hence the wedge-shaped white embolisms often seen in the kidney are not pro-

duced by decolorisation of hæmorrhagic infarctions, but are simply the result of the necrosis of the epithelium, and the halo of injection which is often seen to surround them is due to inflammatory congestion caused by the presence of the necrosed patch.

This explanation of the mode of production of the hæmorrhagic infarction is more closely in accord with the view originally propounded by Virchow, who regarded the hæmorrhage as due to collateral fluxion.

We have now to consider the effects of emboli which possess irritating or poisonous qualities, such as those derived from the puriform softening of venous thrombi in cases of septic inflammation, &c. The mechanical effects will be the same as those of the previous class; but, in addition, these emboli set up a suppurative inflammation in their vicinity, quite independent of any obstruction of the circulation. Hence it is that we meet with pyæmic abscesses, as the result of infecting emboli, in all parts of the body, while the effects of obstructed circulation are, for the most part, confined to certain organs. Thus the liver is very frequently the seat of embolic abscesses, while hæmorrhagic infarctions do not occur there. In the lung where in parts terminal arteries are found but for the most part there is free anastomosis, the two processes are often seen side by side. The different effects of these two classes of embolism are very manifest in the capillaries. Simple emboli, of such small size as to become first arrested in the capillaries, either cause no permanent change at all, or, at most, produce a punctiform hæmorrhage. Infecting emboli, on the other hand, give rise to the milary abscesses so characteristic of pyæmia.

W. CAYLEY.

EMESIS (*émeté*, I vomit).—A synonym for vomiting. *See* VOMITING.

EMETICS (*émeté*, I vomit).—*Strom.*: *Fr. Emetiques, Ger Brechmittel.*

DEFINITION.—Agents that produce vomiting.

EXUFRATION.—Copious draughts of lukewarm water, Mustard, Sulphate of Zinc, Sulphate of Copper, Carbonate of Ammonia, Common Salt, Alum, Chamomile, Tartar Emetic, Ipecacuanha, and Apomorphia.

ACTION.—The act of vomiting consists in the simultaneous spasmodic contraction of the diaphragm and abdominal muscles, and relaxation of the cardiac orifice of the stomach, so that its contents are expelled. When the diaphragm and abdominal muscles contract, but the cardiac orifice remains closed, so that the contents of the stomach cannot escape, the expulsive efforts are termed *retching*. The nervous centre which regulates these movements is situated in the medulla oblongata, and it may be excited either directly by the action upon it of drugs carried to it by the blood, or reflexly by irritation of various nerves. The drugs that act directly upon it have the same action, whether they are introduced immediately into the circulation or absorbed by the stomach. They may thus produce vomiting and evacuation of the stomach without being taken into the stomach at all, and on this

account they are termed *indirect* emetics although they act directly upon the vomiting centre. Such are ipecacuanha, apomorphia, and tartar emetic. Similarly the drugs that excite it reflexly are still termed *direct* emetics, because they are applied directly to the stomach. Such are the sulphates of zinc, copper, and alumina, carbonate of ammonia; salt; mustard; and chamomile, which irritate the nerves of the stomach. Tickling the fauces with a feather, or with the finger, also excites reflex vomiting, and may be adopted either alone, or in order to aid the action of other emetics. The terms *direct* and *indirect*, therefore, as applied to emetics, relate to the stomach and not to the centre for vomiting.

Direct emetics, as they stimulate the nerves of the stomach only, have little action except that of simply exciting vomiting. The *indirect* emetics, which excite vomiting by their action on the medulla oblongata, act also on other parts of the nervous system, and cause secretion of saliva, secretion of mucus from the œsophagus, stomach, and bronchial tubes, and perspiration. They also cause much nausea, depression of the circulation, and loss of nervous and muscular power. Further, the vomiting they induce is more continuous and violent, and often expels the contents of the gall-bladder, causing part of the bile to flow into the stomach, and be thus evacuated.

Uses.—Emetics are employed to remove the contents of the stomach under various circumstances. Firstly, when the food is causing irritation, and not undergoing proper digestion, as, for example, in dyspepsia or sick-headache, and in such cases large draughts of lukewarm water, of mustard and water, or of an infusion of chamomile are usually found beneficial. Secondly, in cases of poisoning, and here mustard, sulphate of zinc, or sulphate of copper are best, as they empty the stomach most quickly and effectually. Thirdly, to cause the expulsion of bile from the gall-bladder, or remove bile from the body in biliousness, fevers, and ague. When the bile-duct is stopped by a small gall-stone, the pressure exerted on the gall-bladder during vomiting has been known to cause the expulsion of the calculus. In biliousness, excess of bile is more readily removed by vomiting than by purging, as there is no opportunity for the bile to be absorbed on its way from the gall-bladder to the mouth, whereas it may undergo absorption on its passage through the intestines. It is supposed by some that various poisons circulate occasionally in the bile, such as the malarious poison which occasions ague, and possibly other septic poisons which give rise to fevers. The advantage of emetics in ague is undoubted, as it can certainly sometimes be cured by them without quinine and the action of quinine is always aided by their use. They have also been recommended in the early stages of continued fevers. In such cases tartar emetic or ipecacuanha are most serviceable. Fourthly, to cause expulsion from the air-passages of false membrane in croup or diphtheria, or of secretions in bronchitis and phthisis. For these purposes ipecacuanha is the emetic most frequently chosen, but if it does not act rapidly in croup sulphate of zinc or sulphate of copper may be employed, and in cases of either croup or

bronchitis where there is great depression of the circulation carbonate of ammonia may be used with advantage, as it not only causes vomiting, but at the same time stimulates circulation.

T. LAUDER BAXTON.

EMMENAGOGUES (ἐμμηνα, the menses, and ἄγω, I move or expel).

Definition.—Emmenagogues are remedial agents which stimulate or restore the normal menstrual function of the uterus, or cause expulsion of its contents.

Enumeration.—Emmenagogues may be either *indirect*, as Iron, Strychnia, and other tonics, Warm Hip baths, Leeches, Mustard Stupes, Aloetic purgatives, &c., or *direct*, as Iru, Borax, Savin, Myrrh, Cantharides, Gumacum, Apioi, Quinine, Digitalis, and Ergot—most of which, when given in larger doses, produce abortion, and are called *Echolics*. The most efficient means, however, of obtaining this last-named action are those of a mechanical nature, so well known to obstetricians, and directed either to the actual rupture of the membranes, or to their separation from the cervix.

Action.—The *indirect* emmenagogues act by improving the quality of the blood, giving tone to the nervous system, or irritating adjacent parts or organs, from which a stimulating influence is conveyed by reflex action to the womb.

The *direct* drugs in moderate doses gently stimulate the uterus, promoting the menstrual flow, or even checking it when in excess; but when further pushed they cause powerful contraction of the unstriated muscular fibres, of which its walls are mainly composed. Ergot, which is the principal, and in fact almost the only really useful member of the group, is believed to act either directly on the muscular tissues themselves, or through the intermediate intervention of some central or peripheral nervous influence.

Uses.—Checked or retarded menstruation frequently results from anemia or general debility, and the indirect emmenagogues will under these circumstances usually effect a cure. If, however, the case prove more obstinate, a little ergot added to the iron will often restore the suspended function. If even this do no good, some mechanical impediment probably exists, or some altered physical condition of the womb which mere drugs cannot rectify. Ergot is frequently employed in cases of lingering labour from simple inertia of the uterus, but its use must be strictly confined to those cases in which there is no marked disproportion between the maternal passages and the head of the child. Advantage is also taken of its contractile powers in the treatment of uterine hemorrhages, or for the destruction of the smaller varieties of polypi, which are so frequently contained within the womb, by cutting off their blood-supply. Finally, it may be necessary, under certain conditions, to induce abortion or premature labour, as when constant sickness, or albuminuria, or compression of adjoining neighbouring viscera seems to endanger the mother's life, or when pelvic distortion renders it impossible for a living child to be born at full term. When the

medical attendant has made up his mind that interference is necessary, he generally has recourse to one or other of the mechanical methods which are fully described in works more particularly devoted to obstetrics.

ROBERT FARQUHARSON.

EMOLLIENTS (*emollio*, I soften).—**DEFINITION.**—Substances that soften and relax the parts to which they are applied.

ENUMERATION.—The principal emollient applications are:—Warm water, Steam, Poultices made of substances which retain heat and moisture, for example, linseed-meal, bread, bran flour, oatmeal, and figs; Fatty substances, as linsed, olive, almond, and nut's-foot oil, lard, and suet, Spermaceti, Wax; Soap Lintment and other liniments; Glycerine; and Paraffines such as vaseline, unguentum petrolei, &c. To these may be added such substances as do not properly relax the tissues, but protect the surface from irritation, such as White of Egg, Gelatine, Isinglass, Collodion, and Cotton-wool.

ACTION.—Emollients relieve the tension and pain of inflamed parts by their action both upon the blood-vessels and upon the tissues themselves. They cause all the contractile tissues to relax and dilate, and thus, lessening pressure upon the nerves of the part, they relieve pain. They soften superficial parts by supplying them with either fat or moisture, and by increasing the supply of blood. In this way they prevent the skin from cracking after exposure to cold. When the cuticle is lost they form a covering, under which the skin may heal, and they prevent the injurious consequences of friction from without.

Uses.—Fatty emollients are used to prevent the skin or mucous membranes from cracking, to prevent irritation or ulceration between parts constantly in contact, as on the limbs of children near the joints; to prevent bed-sores, to aid the healing of blisters, or in skin-diseases, such as eczema. They are also used, especially in the form of linimentum oleum, as applications in burns and scalds, for which purpose such substances as cotton-wool are likewise frequently employed. Mucilaginous substances are useful when swallowed to relieve pain and irritation in the throat, and to lessen irritable cough, and such substances as figs are employed to protect the intestines from injury by hard and pointed substances which have been swallowed. Warmth and moisture are applied in the form of poultices to the surface in pustules, boils, carbuncles, and deep seated inflammation of the limbs, and in inflammation of the internal organs (see POUltICES). In the form of vapour they are useful in inflammation of the air-passages (see INHALATIONS).

T. LAUDER BRIDGES.

EMPHYSEMA of Lungs. See LUNGS, Emphysema of.

EMPHYSEMA, SUBCUTANEOUS (*tu*, in, and *phese*, wind).—SYNON.: Fr. *emphyseme*; Ger. *Windgeschwulst*.—Subcutaneous emphysema is the distension of the spaces of the areolar tissue with air or any other gas. There is thus produced a swelling, in slight cases affecting a very limited area, in extreme cases extending to the subcuta-

neous tissue of the whole body. Unless the tension is great the swelling is slightly lobulated, it is elastic, and although the finger sinks readily into it no lasting impression is left. When the area affected is small, the gas can be driven in any direction by the pressure of the hand. On palpation a peculiar fine crepitation is felt, which is absolutely diagnostic. On percussion there is superficial resonance, the note resembling that obtainable from a bladder loosely filled with air. Unless the gas causing the emphysema is the product of decomposition of gangrenous tissues, as in spreading gangrene there is no redness of the skin. The swelling usually forms rapidly and may extend in a few minutes over the greater part of the body. In such cases it is most marked where the subcutaneous tissue is lax. In the face the features are obliterated, and the eyes closed by the swelling of the lids. The scrotum and penis become enormously distended.

ÆTIOLOGY AND PATHOLOGY.—Wound of the lung from a broken rib or from a stab is the most common cause of subcutaneous emphysema. If from a stab, it can only occur when the opening is in the pleura and that in the skin no longer correspond with each other, in consequence of an alteration in the position of the patient, or when the wound has been artificially closed. When from wound of the lung it may occur with or without pneumothorax. Nothing is more common than to find a limited emphysematous swelling round a fractured rib without any signs of air in the pleural cavity. This arises either from adhesions existing between the parietal and visceral layers, or from the escape of air being very limited. In severe cases with pneumothorax the mechanism of the production of emphysema is as follows:—A wound in the lung always allows air to pass from it readily, but from the way in which the soft pulmonary tissue falls together, no amount of force can drive air through the wound in the opposite direction. It thus acts somewhat like the valve of an air-pump. The first effect of the escape of air into the pleural cavity is to cause collapse of the lung. As the chest expands with each inspiration air rushes from the wound in the lung into the pleural cavity, as it contracts in expiration, the air, being unable to pass back by the wound, is driven through the opening in the parietal pleura into the subcutaneous cellular tissue. In such cases there is gradually increasing dyspnoea, with great distension of the subcutaneous cellular tissue, and unless relief is given the patient dies asphyxiated.

Emphysema occasionally occurs from rupture of some of the air-vesicles during a violent expiratory effort. Waicbe states that this accident has happened from 'the efforts in parturition, defecation, raising weights, coitus, violent coughing, paroxysms of rage, excessive laughter, and hysterical convulsions.' The air usually escapes first into the cellular tissue between the lobules of the lung, giving rise to the condition known as *interlobular emphysema*. It then finds its way into the mediastinum and from thence to the root of the neck. Interlobular emphysema gives rise to intense dyspnoea, and has been known to cause sudden death. Emphysema has also been seen as a consequence of ulceration of the trachea, and in a few very rare cases as the

result of ulceration proceeding from a cavity in the lung through the adherent pleura and intercostal muscles to the subcutaneous cellular tissue.

Localised emphysema of the face is a symptom of fractures implicating the antrum.

Emphysema of the flanks is an occasional symptom of rupture of the third part of the duodenum, or hind the perigonum, and of perforation of the cæcum at its posterior part.

Emphysema of the perineum and scrotum may arise from a wound of the bowel in the administration of an enema.

In non-penetrating wounds of the thorax and abdomen, a small quantity of air may find its way into the areolar tissue in the immediate neighbourhood, in consequence of the movements of respiration. In compound fractures emphysema is often found extending some distance above and below the wound if the patient has been carried some distance and the injured limb much shaken.

Emphysema from the gases produced by decomposition is only seen in cases of rapidly spreading moist gangrene.

PURGERS AND TERMINATIONS.—The effects of emphysema differ with the source of the gas. When the air comes from a superficial wound of the lung, it has no tendency to cause decomposition of the effused blood with which it may come into contact. Thus, in surgical cases, no evil consequences result from emphysema around a simple fracture of a rib. This is explained by the fact that the gas in the air-vesicles is absolutely free from solid particles of any kind, as shown by Tyndall's experiment, in which the residual air, in forced expiration, makes a gap in the beam of an electric light when breathed across it. On the other hand, air admitted from without, as in a compound fracture, tends to favour the decomposition of the effused blood, and renders treatment by occlusion or by antiseptic dressing difficult and uncertain. In ordinary cases the effused air is rapidly absorbed without causing inconvenience of any kind. If the amount of air in the tissues be very great, and the case be complicated by pneumothorax, fatal dyspnoea may occur, unless relieved by treatment.

TREATMENT.—The swelling itself requires usually no treatment, the gas being absorbed without difficulty. If it is complicated by pneumothorax, or if the dyspnoea be such as to threaten death, the wound, if one exists, must be opened up, or, if there is none, a free opening must be made into the pleural cavity. If the swelling be such as seriously to inconvenience the patient, a few punctures may be made with a triangular needle. Emphysema from intestinal flat is always limited, and requires no treatment beyond that applicable to the cause of the escape of gas. MAURICE BICK.

EMPIRICAL (*ἐμ, by, and πείρα, experience*)—This term is applied to treatment founded on experience, as opposed to *rational*, founded on scientific reasoning. See **DISEASE, Treatment of**.

EMPROSTHOTOS (*ἐμπροσθεν, forwards, and τείνω, I stretch*)—A bending or drawing forwards of the body, due to tonic contraction of the muscles, observed in some cases of tetanic convulsions. See **TETANUS**.

EMPYEMA (*ἐμ, in, and πύω, pus*).—Strictly speaking this term signifies a collection of pus within the cavity of the pleura, but it is often conventionally used to denote any inflammatory effusion in that situation which has assumed a chronic character. See **PLEURA, Diseases of**.

EMS, in Germany.—Thermal mineral alkaline waters. See **MINERAL WATERS**.

ENCEPHALITIS (*ἐγκέφαλος, the brain*).—Inflammation of the brain and its membranes, or, more properly, inflammation of the brain-substance itself. See **BRAIN, Inflammation of**.

ENCEPHALOCLE (*ἐγκέφαλος, the brain, and κλην a tumour*)—A hernial protrusion of a portion of the brain-substance through an opening in the skull, which may be either congenital or the result of accident. See **BRAIN, Malformations of**.

ENCEPHALOID (*ἐγκέφαλος, the brain*).—A form of cancer, so named on account of its obvious resemblance to brain-tissue. See **CANCER**.

ENCHONDROMA (*ἐν, in, and χόνδρος, cartilage*)—A new-growth consisting of cartilaginous tissue. See **TUMORS**.

ENCYSTED (*ἐν, in, and κύστις, a bladder*).—Contained within a cyst. A term applied to new-growths or collections of fluid thus enclosed.

ENDARTERITIS (*ἐνδον, within, and ἀρτηρία, an artery*)—Inflammation of the internal coat of an artery. The disease is generally chronic or subacute rarely acute. Two special forms of endarteritis have been described, namely, *endarteritis deformans*, or *atheromatous disease* (see **ARTERIES, Diseases of**, and **ATHEROMA**), and *siphilitic endarteritis*, which most frequently affects the vessels of the brain, but the specific nature of which has lately been questioned (see **SYPHILIS**, and **BRAIN, Vessels of, Diseases of**).

ENDEMIC (*ἐν, in, and δῆμος a people*).—This term is applied to diseases that prevail in particular localities or districts, and which are due to special etiological conditions existing there. See **DISEASE, Causes of**.

ENDERMIC (*ἐν, in, and δέρμα, the skin*).—A term generally applied to the method of introducing remedies through the skin. The horny layers of the cuticle interpose so effective a barrier between most remedial agents and the absorptive surface of the true skin, that the endermic plan of treatment when introduced was looked upon as a therapeutic gain. The ease with which drugs could thus be administered, and the excellent results obtained in neuralgia and other nervous affections, were held to far more than counterbalance the pain of the application, the resulting disfigurement, and the occasional troublesome ulceration which ensued. And, although the hypodermic syringe, with its greater rapidity and efficiency, has rendered the endermic method almost obsolete, there are still circumstances which might induce us to use it. For instance, a blistered surface might be ready to hand; or it might be considered advisable to combine counter-

irritation with the subsequent local use of morphia or other sedative drugs; or it might not be possible to procure an instrument for subcutaneous injection, or an invincible objection might be made to the needle-prick, which is sometimes a source of apprehension to sensitive natures, and we might then be glad to avail ourselves of a moderately efficient substitute.

MODE OF APPLICATION.—We detach the epidermis either by any ordinary blistering application, or by the button-cautery, and after its careful removal, we apply our selected drug to the raw surface, in the form either of powder or of an ointment, which latter plan has seemed to the writer rather more efficient, as ensuring more prolonged contact, the application being also less easily washed away by the effusion of serum from the skin. The principal remedies used in this way have been morphia, which, in doses of from a quarter of a grain to two grains, is undoubtedly beneficial in cases of neuralgia, sciatica, and localized rheumatism; strychnia, which was formerly much employed in amaurosis, lead palsy, infantile paralysis, and other nervous affections, in doses of from $\frac{1}{15}$ grain to one grain, and quinine, which in 6-grain doses has apparently cured obstinate cases of ague.

ROBERT FARQUHARSON.

ENDOCARDITIS (*ἐνδο*, within, and *καρδία*, the heart).—Inflammation of the lining membrane of the heart. See HEART, Inflammation of.

ENDOGASTRITIS (*ἐνδο*, within, and *γαστήρ*, the stomach).—Inflammation of the mucous membrane of the stomach. See STOMACH, Diseases of.

ENDOMETRITIS (*ἐνδο*, within, and *μήτρα*, the womb).—Inflammation of the lining membrane of the uterus. See WOMB, Diseases of.

ENDOPERICARDITIS.—Inflammation of the endocardium and pericardium together. See HEART, Inflammation of; and PERICARDIUM, Diseases of.

ENEMA (*ἐνίμν*, I inject).—SYNON.: Lavement; Clyster; Fr. *Clystère*; Lavement; Ger. *Klyster*.

DEFINITION.—An enema is a liquid injected by means of a suitable instrument into the rectum or the colon.

INSTRUMENTS.—Various instruments are used for the administration of enemata:—1. A simple elastic bottle with ivory or gum-elastic pipe, which has superseded the old bag and pipe. 2. An india-rubber bottle with flexible tube at either end and double action. 3. An ordinary piston syringe, worked by the hand, which is either simple, or provided with a double action, so as to supply a continuous stream. The simplest enema made by Messrs. Arnold is very convenient; the piston works on a spring, and requires no packing. 4. A French instrument, known as the *irrigateur*, worked by a spring. 5. The hydraulic enema, which consists of a piece of india-rubber tubing about six feet long, furnished with an ordinary ivory rectum-pipe at the one end, and a metal cone, or a screw nozzle,

at the other. The tube, being filled with the injection, has one end placed in the containing reservoir, or is connected by the screw, while the pipe at the other end is introduced into the bowel. The vessel supplying the injection being placed on an elevation, the liquid gravitates into the bowel, filling the large intestine. When it is desirable to inject a large quantity the patient should lie first on the left side, then on the back, and lastly on the right side, to promote the filling of the whole intestine. In all cases care should be taken to prevent the injection of air into the bowel, and also to ascertain that the nozzle of the injecting pipe is free in the rectum, not thrust against the sacrum, or into a hard fecal mass.

VARIETIES AND USES.—The chief varieties and uses of enemata are as follows:—

1. **Anthelmintic Enemata.**—To cure thread-worms injections of salt and water, or lime-water, or from two to four drachms of spirits of turpentine diffused by yolk of egg in four ounces of water are serviceable. The enema of aloes or of asafoetida may also be employed in the small quantity just named.

2. **Antispasmodic Enemata.**—Puerperal convulsions have been relieved by the injection of half a drachm or more of chloral hydrate. Injections of asafoetida or of rue are also given. Injections of warm water with 5ij or 3iij of sulphuric ether have sometimes relieved spasmodic invagination of the bowels. When the intestine is tympanitic and distended, the enema terebinthine acts well as a stimulant and carminative.

3. **Astringent Enemata.**—These are used either to check diarrhoea, to arrest hæmorrhage, or to cure ulceration and mucous discharges. For the first of these purposes the enema opii is valuable. In cases of hæmorrhage from the bowels, as well as from the womb, injections of ice-cold water are frequently used. Ulceration with mucous discharge is often successfully treated by enemata of nitrate of silver (five grains to one pint of distilled water), of sulphate of zinc or alum (one or two grains to the ounce of water), or of sulphate of copper (one grain to the ounce of water).

4. **Emollient Enemata.**—Demulcents, such as decoctions of starch, linseed, or barley, or pure linseed oil, are at times used with the object of imparting nourishment to the system, and of soothing an irritable mucous membrane.

In dysentery, from four to six pints of warm water, or of milk and water, have been injected as an internal fomentation.

5. **Nutrient Enemata.**—In cases of exhaustion enemata of beef-tea and eggs beaten up are used; about four or six ounces should be given at once. Should the rectum become irritable, the irritability may be often lessened by adding a few drops of laudanum to each enema. De fibrinated blood, in its recent or dried form, has lately been recommended as a material for nutrient enemata (see paper by Dr. Sanson on Supplementary Alimentation, *Lancet*, 1881, vol. i. p. 288). The digestion and assimilation of nutrient enemata may be facilitated by the addition of preparations of pancreas and pepsine. See PEPTONISED FOOD, page 1116.

injections of brandy and water, or beef tea and brandy, have been given with benefit in prostration from uterine hemorrhage.

6. **Sedative Enemata.**—These are often employed in painful affections of the rectum and bladder. The enema opii, containing half a drachm to a drachm of tincture of opium, is well suited. In spasm of the bowels and in hernia the enema taluci may be resorted to, but it may produce faintness and collapse. An infusion of twelve grains of dried belladonna leaf in six ounces of shot water is also used with advantage.

7. **Purgative Enemata.**—These are used to overcome constipation. For this purpose—in the case of an adult—from one to two pints of fluid must be slowly pumped into the bowel. If the process be conducted gradually, stopping occasionally and making pressure on the anus if the injection threaten to come away, as much as four or five pints can be got into the bowel. The injection should be retained as long as possible, as thus a complete evacuation is insured. As a general rule about a pint of liquid is enough for an adult; for an infant an ounce, for a child of four years, four to six ounces.

Composition.—Soap and water, gruel with olive oil, castor oil, and sometimes oil alone, may be used. The enema magnesie sulphatis contains one ounce of epsom salts, and is an efficient purgative. Enema aloes is also recognised. In cases of intestinal obstruction the introduction of a large volume of soap and water—with oil, perhaps, added—by means of the gravitation-tube, may be had recourse to with advantage. Obstruction due to impacted feces generally yields to this method of treatment.

The frequent use of very large injections is undesirable, lest undue distension result. The frequent use of injections washes away the mucus designed to lubricate the bowel.

JOHN C. THOROWOOD.

ENGADINE, UPPER, in Switzerland.—A bracing mountain climate. Elevation of valley 5 000 to 6,000 feet. Season, June to September. See CLIMATE, Treatment of Diseases by.

ENGHIEN, in France.—Sulphur waters. See MINERAL WATERS.

ENGLISH CHOLERA.—A synonym for simple cholera or choleraic diarrhoea. See CHOLERAIC DIARRHOEA.

ENGORGEMENT.—Overloading of the vessels, or of the heart, with blood. A synonym for congestion. See CIRCULATION, Disorders of.

ENTERALGIA (*ἔντερον*, the intestine, and *ἄλγος*, pain)—SYNON: Enterodynia; *Acutalga menenterica vel menenterica*; Colic.

The terms enteralgia and colic—generally regarded as synonymous—include all forms and degrees of paroxysmal intestinal pain in cases where there is no febrile disturbance. Enteralgia, implying more especially the neuralgic nature of the sensori-motor disturbance, is sometimes preferred, as by those who hold that colic proper—of which levi-colic is a typical example as distinguished from symptomatic colicky pains—

is a visceral neuralgia. It is likewise frequently applied to colic occurring in neurotic, anæmic, anæmic, or gouty subjects, even when there is a local exciting cause, such as flatulæ, retained feces, &c.; and to conditions in which pain predominates over spasm. The clinical features of enteralgia are, however, indistinguishable from those of colic; a similar local disturbance, according to its intensity, is reflected by the nerves to the heart and the peripheral arteries—the action of the former becoming slow and feeble, and the latter contracting, hence arising the small, infrequent, tense pulse, the cool pale skin, and the other signs of collapse which mark the distant effects of colic; and, as in this disorder, the termination of the attack may be sudden, perhaps following the expulsion of flatulæ or feces—a free perspiration, a copious flow of pale urine, the menstrual or lochial or other discharge, or a fit of the goat.

TREATMENT.—The main indications in the treatment of enteralgia are to endeavour to remove any cause of the pain; and to administer opium or other anodynes for the relief of the suffering. See COLIC, INTESTINAL.

GEORGE OLIVER.

ENTERIC FEVER.—A synonym for typhoid fever. See TYPHOID FEVER.

ENTERITIS (*ἔντερον*, a bowel).—Inflammation of the intestines. See INTESTINES, Diseases of.

ENTEROCOELE (*ἔντερον*, a bowel, and *κύλη*, a tumour)—A hernia containing a portion of bowel. See HERNIA.

ENTOPHYTE (*ἐντός*, within, and *φύτις*, a plant)—A plant parasitic in any part of the body. *Entophytic Dueses* are diseases that are supposed to depend upon the growth of such plants, as, for example, fungus-foot. See FUNGUS FOOT OF INDIA.

ENTOZOA (*ἐντός*, within, and *ζῷον*, an animal).—This term not only embraces all the animal parasites coming under the category of 'worms, or 'intestinal worms,' but also a great variety of creatures which take up their residence in the soft and hard tissues as well as in the cavity of the digestive organs of their human and animal bearers. Under the article PARASITES is given a definition which will probably be found more comprehensive than any hitherto offered. In this place, with the double view of facilitating reference and supplying an epitome of the whole subject, a complete alphabetical list of the separate headings under which the entozoa are discussed in the body of this work is appended. The articles stand as follows:—Acephalocystis, Ascarides; Bilharzia; Bladder-worms; Bothrioccephalus; Chigoe (Sandworm); Cysticercus; Demodex; Distoma; Dracunculus, Echinococcus; Echinorhynchus; Fasciola; Filaria; Filaria Sanguinis-Hominis; Fluke; Guinea-worm; Hematodes (Blood-worms); Helminths; Hydatids; Intestinal worms; Lambricus; Measles; (Estrus (Bots, Maggots, Insect Parasites, Gadfly); Oxyuris; Parasites; Penetration; Round-worms; Sclerostoma (Analysic-tomum Doehmii); Seal-worm; Tænia; Tape-

worm; Thread-worm; Trichina; Trichinosis; Trichocephalus; Vermes; Whip-worm.

The *Entozoa* are noticed under the article *Entozoa*. T. S. CORNHOLD.

ENTOSOMON FOLLICULORUM.—A synonym of the animalcules of the follicles of the skin, otherwise named *acarus* (Simon), *demodex* (Owen), and *stentosomon folliculorum* (Erasmus Wilson). See *ACARUS* and *DEMODEX*.

ENTROPION (*ἐν, in*, and *τρέπω, I turn*).—A morbid condition in which the eyelid is inverted, so that its free margin is directed towards the eye. See *ERS* and its Appendages, *Diseases of*.

ENURESIS (*ἐν, in*, and *ὑέρω, I pass the urine*).—Involuntary discharge or incontinence of urine. See *MICTURITION, Disorders of*.

EPHELIS (*ἐπι, due to*, and *ἥλιος, the sun*).—*STYON*; Sunburn; Fr. *Ephélide*, Ger. *Sonnenflecken*.—This word is applied to pigmentary discoloration of the skin, of a brown, grey, or black colour, resulting from the stimulus of light and heat, as of the sun's rays, or scorching by fire. Two principal varieties of the affection have been noted, namely, *Ephelis solaris*, and *Ephelis ignalis*. See *PIGMENTARY SKIN-DISEASES*. ERASMUS WILSON.

EPHEMERAL FEVER (*ἐφ', upon*, and *ἡμέρα, a day*).—A mild form of milk-fever, so called on account of the rapidity with which it subsides, lasting not more than a day. See *MILK-FEVER*.

EPIDROESIS (*ἐπι, upon*, and *ἰδρῶς, I sweat*).—A term signifying a state of sweating, and synonymous with *Idrosis*. See *PERSPIRATION, Disorders of*.

EPIDEMIO (*epidemios*, affecting the people, from *ἐπι, upon*, and *δῆμος, a people*).—The word *epidemic* is used in two senses by medical writers and by medical men, namely, (1) in a general sense, and (2) in a technical sense.

As a *general term* the word signifies 'common to, or affecting, a whole people, or a great number in a community; prevalent; general.' (*Webster's Dictionary*.) It is in this sense that the word is used when it is applied to mental, moral, and social phenomena, as, for example, when we speak or write of 'epidemic suicide,' 'epidemic folly.' This employment of the word is consistent with received literary practice. Thus we read, 'There was a time when *vet* was epidemic.' (*Alibonsum*.) Again, M. Littré, writing to *Le Temps*:—'It argues great confidence in oneself and one's own enlightenment to treat with haughty disdain, and without reserving any compromise, the opinion of so many citizens, and to regard it as a case of epidemic aberration.'

As a *technical term* having reference to disease the word *epidemic* has several different meanings attached to it. All these meanings include the notion of general prevalence among a community or a people, but some of them would go on, beyond what etymology justifies, to attach a peculiar hypothetical or theoretical conception to the term. Thus (a) Mayne restricts the term to diseases which are contagious, making contagious the essence of *epidemicity*, as he would phrase it; (b) Dunglison implies by the term a

particular constitution of the air ('*constitutio aeris*, or condition of the atmosphere'). (c) other authoritative writers use the term as signifying a widespread cause, telluric, atmospheric, cosmic, as the case may be, acting at the same moment of time on many individuals, or as something occult, regarding which speculation is vain, and which they designate *epidemic constitution* or *epidemic influence*.

The foregoing technical significations attached to the word *epidemic* are not less misleading than insufficient. Mayne's definition implies an arbitrary limitation upon the meaning of the word, while it involves but a partial notion of the phenomena of epidemic prevalence of contagious diseases. Dunglison's definition does not rest upon a scientific foundation, and its phraseology, derived from a period when medicine was still hampered with semi-mystical speculations, cannot well be dispossessed of the vague traditional meanings which adhere to the word 'constitution.' Other technical definitions (if that can be called a definition which makes obscure what should be rendered clear) rest on more assumptions or relegate the term to the incomprehensible and insoluble. Of these last-named definitions Léon Colin has recently said:—'They signify implicitly a common cause, apparently indecomposable, to which individuals are not exposed successively but simultaneously . . . something isolated, impersonal, inaccessible to reason, detached from the disease itself, the epidemic genus [constitution, influence] . . . a creative force of the different epidemic affections, compelling, directing, extinguishing them.'

The promiscuous use of the word *epidemic* in medical literature and medical talk, and the different irreconcilable significations attached to it as a technical term, have been, and still continue to be, sources of almost hopeless confusion in treating of diseases in respect to which the phenomenon of (etymologically) epidemic prevalence is observed. It is not difficult to apprehend how this has come about. The diseases in question (the *morbi populares* of some writers) include among them number plague, the eruptive and continued fevers, influenza, malignant cholera, &c. 'They have the peculiar character of attacking at intervals great numbers of people within a short period of time, they distinguish one country from another, one year from another, they have proved epochs in chronology; and, as Niebuhr has shown, have influenced not only the fate of cities, such as Athens and Florence, but of empires, they decimate armies, disable fleets; they take the lives of criminals that justice has not condemned; they redouble the dangers of crowded hospitals; they infect the habitations of the poor, and strike the artisan in his strength down from comfort into helpless poverty, they carry away the infant from the mother's breast, and the old man at the end of life; but their direct eruptions are excessively fatal to men in the prime and vigour of age.' (WM. FARR.) Exercising at all times in their greater and more fatal prevalence the profoundest influence over the mind, as well of the people generally as of the medical profession, these diseases partly from the terror

they inspire, partly from the extreme complexity of the phenomena they display, have formed a never-ceasing subject of the wildest speculation. No part of medicine has retained so much of the semi-mystical teachings of the older physicians as that which relates to epidemics, and general history has contributed with medical history to propagate in regard to epidemics that habit of thought which refers the unknown to the occult—using the latter term in the sense in which it is applied with regard to the imaginary sciences of the Middle Ages. Much of the speculation as to epidemics which passes current for science at the present day is in reality an unsuspected continuation of the mystical teachings of earlier medicine: magnetism, or electricity, for example, taking the place of Saturn or Mercury in the scheme of causation. The terminology is modernised, but the underlying conception remains the same. Again, the so-called 'precursors' of epidemics which still find a place in treatises on medicine are the relics of the doctrine of portents of the Middle Ages. They rest on the assumption of an epidemic being determined by some common extra-murine or intra-murine cause, of which it is but one of several effects. The celestial 'portents,' such as comets and meteors, and the more manifest telluric 'portents' such as earthquakes and volcanic eruptions, have been discarded, but the 'portents' derived from exceptional developments of insect life, from murrain, from unusual prevalence of certain diseases, and from remarkable perturbations of the weather, are retained under the denomination of 'precursors.' For example, the earlier epidemics of malignant cholera which visited Europe were believed to have been heralded by an unusual prevalence of 'fevers' and of diarrhoeal affections. The epidemic of 1865-66 gave an excellent opportunity of studying the facts bearing on this question. Europe was taken by surprise when cholera appeared in 1865, on the south coast of the Mediterranean, at Alexandria, and began thence to extend rapidly to the southern and eastern shores of that sea. It was not, indeed, until the disease had effected a lodgment in several parts of the Continent that the attention of governments and the public with regard to it was fully aroused. No change of the public health in the several places visited by the epidemic had occurred of such a nature as to give rise to any, even the least suspicion, of impending pestilence. Moreover, notwithstanding the prevalence of steppe murrain and of cerebro-spinal fever in Northern Europe at the beginning of 1865, there was nothing to suggest (indeed it was not suggested) that these phenomena were 'precursors' of the coming epidemic of cholera, or of the extension of yellow fever to the shores of England the same year. In fact, the different occurrences were parts of contemporaneous rather than successive phenomena. The condition of the public health preceding the appearance of cholera in England, and especially in respect to diarrhoeal antecedents, was made the subject of careful study by the late Professor Parkes and others. These observers failed to obtain any intimation of a change in the public health which could be re-

garded as presaging pestilence—of the existence, in short, of any so-called 'epidemic constitution.' It is true that John Sutherland had described an increase of 'fevers' and diarrhoeal diseases in Malta, as preceding the appearance of cholera there, in June 1865, observing that:—'These facts are sufficient to show that long before cholera began to come towards the north-west, there were indications of a changed condition of the public health in Malta;' and after giving an account of two groups of choleraic cases which occurred in Mav, he adds, 'It appears to me scarcely possible to escape from the conclusion that long before cholera appeared in Malta, possibly before the first outbreak in Arabia, the earliest wave of the coming epidemic had passed over those islands.' But while, according to Dr. Sutherland, the coming epidemic was thus clearly foreshadowed in Malta, no change in the public health presaged its appearance in Gibraltar in July. The absence of all foreshadowing of the epidemic at Gibraltar can hardly be reconciled with the suggested presence of such foreshadowing at Malta. The facts which have been interpreted as presaging the appearance of cholera in the latter island are, indeed, to be regarded as coincidental rather than related. It is true, also, that MM. Didot and Guén have endeavoured to show that prior to the appearance of cholera at Alexandria in 1865, choleraic disease existed in Marseilles, and that the outbreak of the epidemic in the latter town was preceded by 'une constitution médicale cholérique.' The evidence they advance in support of their conclusions simply shows that deaths from infantile cholera, which, as they properly remark, is 'à la vérité, fréquente à Marseille,' and from so-called 'sporadic' cholera are apt to occur in Marseilles during the months of May and June, as perhaps in every city and town of southern and central Europe.

Another illustration to the same effect as the above, in regard to the 'precursors' of epidemics, is furnished by the history of the small-pox epidemic of 1869-73, the greatest epidemic of this disease in recent times—a true pandemic (*πάδημος*, from *pā*, all, and *dēmos*, the people) extension of the malady. The astute observers were taken by surprise with the malignity and diffusibility of the disease during the epidemic—phenomena wholly unforeseen. Here, again, the study of the diseases preceding or accompanying the epidemic yields no facts of variation in their prevalence, from which the approach of a great epidemic might have been inferred, nor give any hint that they were dependent with it on some common cause.

There were *concurrent* phenomena of disease during both epidemics, but they were concurrent of certain diseases existing at the same time among the population affected by the great epidemic, and some of them probably having certain secondary elements of causation in common. This is a different question to that of an assumed 'epidemic influence' or 'epidemic constitution.' The subject of the *concomitance of epidemics* is a new field of investigation, which has lately been opened by an arithmetical study of George Buchanan's, relating to epidemics in numerous extra-metropolitan registration sub-

districts in England. This study was directed to ascertain—as necessarily introductory to a statistical investigation regarding community of causation or mutual antagonism of various epidemics—the arithmetical probability of their concurring as a mere matter of chance. The data used were taken from a particular quarterly return of the Registrar-General, and they extended to 946 occurrences of epidemics (small-pox, measles, scarlet-fever, diphtheria, whooping-cough, fevers, and diarrhoea and simple cholera) in 1,400 districts. The result showed a good deal of general correspondence between the calculated number of concurrences and the actually observed number but with departures, of more or less magnitude, of the actual from the calculated degree of concurrence, which deserve to be followed up by further investigation. The departures were shown in an excessive frequency of the concurrence of measles with the other epidemics, of diarrhoea with all other epidemics except small-pox, and of scarlet-fever with the 'fever' of the Registrar-General. On the other hand, it is of interest to observe that there was an absence of any notable excess of frequency of concurrence between scarlet-fever and diphtheria, or between scarlet-fever and whooping-cough.

In view of the extreme looseness with which the word *epidemic* is used in medicine, sometimes simply as a descriptive term, sometimes as a technical or quasi-technical term involving various hypothetical and theoretical conceptions inconsistent with each other, and sometimes as implying an occult influence, it would be well if it could be discarded from medical literature and language. *Epidemic*, in its present medical use, is an instance of words which, as Bacon says, when writing of the effects exercised by a bad and inapt formulation of words on the human mind, 'force the understanding, throw everything into confusion, and lead mankind into vain and innumerable controversies' (*Nov Org* App. 43). But the retention of the word, from its long and familiar usage, is practically a necessity in medicine; moreover, it would be difficult if not impossible to find a substitute which, if the word be used in its ordinary signification, would supply its place.

It is suggested here that the technical meaning of the word epidemic should be assimilated to the common meaning; or, more accurately, that the technical meanings now attached to the word should be abandoned, and the word used in medicine in the same sense as in general literature and in ordinary converse; that is to say, as a merely quantitative term applicable to particular phenomena, whether pathological, mental, or social, in so far as they are 'common to a whole people, or to a great number of a community;' or in a word are 'prevalent' or 'general.' In this way not only would the confusion arising from the present medical uses of the word be got rid of, but the scientific study of epidemic phenomena would be facilitated in the only direction which gives promise of successful issue. As Léon Colin has aptly written:—'It is the disease which constitutes the epidemic, not the epidemic the disease. The evil always remains the same, the number of affected

alone being increased.' The medical study of epidemics is essentially a study of the individual diseases which are apt to become epidemic, and not, as has been too commonly the case hitherto, of some figment of the imagination (*epidemic constitution, or influence, or graine*), apart from the diseases. It is only in proportion as researches have been directed to particular diseases liable to become epidemic, and to the conditions under which they prevailed epidemically, that recent advances in our knowledge of epidemics have been made. In this country the two most important events which have occurred in this connection of late years were the discrimination of *typhus* from *typhoid*, by A. P. Stewart and Wm. Jenner, and the researches on the *typhus of horned cattle* (*steppe-murain, cattle-plague*), promoted by the Royal Commission of 1865-66, on Cattle-Plague. The discrimination of *typhus* from *typhoid* proved that the voluminous speculations which to that time were current on the epidemiology of the continued fevers of this country, then regarded as but one disease presenting several varieties, were for the most part meaningless verbiage, by showing that the two most common forms of fever were distinct diseases clinically, pathologically, and aetiological. This discovery proved to be the inauguration of a true method of investigation concerning epidemics, by making evident that epidemic phenomena did not admit of accurate study, except in so far as it was based upon a just discrimination of the diseases manifesting them, and upon their clinical and pathological histories. The same lesson was taught, not less clearly, although in another fashion, by the researches promoted by the Royal Commission on Cattle Plague with which the names of Lionel Beale and Barlow Sanderson are especially connected. These researches demonstrated the essentially infectious nature of the malady, and that its prevalence was dependent upon the dissemination of the infection, directly or indirectly, from animals sick of the disease to the healthy. It was shown, indeed, in the pathological laboratory, that preconceived doctrines of some occult epidemic influence which had been submitted to the Commission as determining the prevalence of the cattle-plague had no existence in fact when the disease was subjected to experimental study, and that its conditions of prevalence were fully within human control. These researches proved the starting-point of those important investigations on the intimate pathology of contagion carried out by Barlow Sanderson and Klein, for the Privy Council, under the direction of John Simon, and to which Wm. Roberts and others have independently contributed so largely—investigations which promise speedily to revolutionise our knowledge of the intimate pathology of infectious diseases. It is interesting to note that the Royal Commission on Cattle-Plague included the following medical members:—Richard Quain (M.D.), H. Benet Jones, E. A. Parkes, T. Wormkld, and R. Ceely. TESTES, Diseases of.

EPIGASTRIC REGION.—This region is
situated at the upper and central part of the
abdomen, just below the ensiform cartilage, and
between the sloping margins of the thorax down
to the level of the ninth cartilage, corresponding
to what is popularly known as the 'pit of the
stomach.' The structures within the abdominal
cavity which normally occupy the epigastrium
are the greater part of the stomach, a small
portion of the liver, and more deeply a part of
the pancreas, the aorta giving off the coeliac axis
and superior mesenteric branch, the vena cava
inferior, the veins forming the commencement of
the portal vein, the receptaculum chyli, and the
solar plexus.

CLINICAL INVESTIGATION.—Clinically, it will
be found that patients frequently complain of
abnormal sensations especially referred to the
epigastrium. These are generally associated with
the stomach, and may merely amount to a sense
of discomfort, fulness, or tightness, or to actual
pain of varying character, more or less severe
according to the condition upon which it de-
pends, and often much influenced by the inges-
tion of food. Sensations of trembling, throbbing,
or sinking in the pit of the stomach are also
of common occurrence, especially in females.
These are often merely of a nervous character.
In some cases there is evident tenderness, either
over the entire epigastrium or in some limited
spot, and it is important to recognise whether
this is superficial or felt more or less deeply, for
it may be connected with the superficial struc-
tures, the peritoneum, the liver, the stomach,
or the pancreas. The sensation experienced in
connection with hunger is referred mainly to the
epigastrium, and it may be of a painful cha-
racter. Here may also be noticed the epigastric
pain termed *gastralgia* or *gastrodynia*, which
is usually felt chiefly when the stomach is
empty, being relieved by taking food. A most
unpleasant sensation at the pit of the stomach
accompanies nausea, which may be of a horrible
but indescribable character, while violent vomit-
ing or itching causes considerable pain or itching
in this region, partly associated with the stomach,
partly with the abdominal walls. Heartburn is
another sensation which seems to start from the
epigastrium. Sometimes the pain is situated
deeply, or shoots towards the back. This may
depend upon disease affecting the posterior wall
of the stomach, pancreatic disease, aneurism, or
other causes. A sensation of tension or actual
pain is sometimes experienced just below the
ensiform cartilage in cases where the diaphragm
is much pressed downwards, as from extreme

emphysema, abundant accumulation of fluid or
air in the pleura, or extensive pericardial effusion.
A deep pain is not uncommonly referred to the
epigastrium in cases of Addison's disease, and
also in those of pernicious anaemia. Probably
this is connected with the sympathetic plexures.

Physical examination of the epigastric region
is often of the greatest value, and important
objective signs of various morbid conditions may
thus be readily recognised. Of course organs
which are normally confined to other regions may
enlarge so as to extend into the epigastrium, or
may become very movable and consequently be
felt in this region. It may, moreover, be occu-
pied, along with other parts of the abdomen, by
growths or accumulations of fluid. The objec-
tive signs and conditions which are more espe-
cially connected with the epigastrium may be
indicated as follows—

1. It is customary to apply the hand over the
epigastrium for the purpose of counting the
respirations, if these cannot be reckoned by
merely watching the patient breathing.

2. Morbid conditions of the abdominal walls
may be confined to the epigastric region, such as
an abscess, and here it may be remarked that the
recti muscles frequently become very hard and
rigid when palpation is practised over this part,
and so might be in danger of being mistaken for
some serious lesion, unless care were exercised
in the examination.

3. Growths connected with the peritoneum,
especially the great omentum, may be felt chiefly
or entirely in the epigastrium in some instances.

4. Abnormal states of the stomach are neces-
sarily revealed mainly by corresponding signs in
the epigastrium. Thus there may be evidence of
dilatation of this organ, carcinomatous infiltra-
tion of its anterior wall, a localised tumour; or
of some accumulation in its interior, whether
solid or liquid. It must be remarked, however,
that the stomach, when diseased, frequently
extends into other regions beyond the epiga-
strum.

5. When the liver is the seat of organic disease,
this is often revealed in the epigastric region,
usually along with other regions, but sometimes
the abnormal physical signs are noticed specially
in this part. Thus a cancerous mass may present
here, or a hydatid tumour or hepatic abscess may
tend in this direction. The gall-bladder has also
occasionally been found, when the seat of some
accumulation or of malignant disease, to have
been displaced towards the epigastrium and be-
come fixed there.

6. Pulsation is not uncommonly felt in the
epigastrium. When situated at its upper part,
just below the ensiform cartilage, it depends
upon the heart, usually its right side, being due
either to shortness of the sternum, displacement
of the heart, or enlargement of its right cavity.
Very often a pulsation is felt, and sometimes even
seen, due to a pulsating aorta; and an impulse
from this vessel may be transmitted through an
enlarged pancreas, or through an abscess of the
liver, of which the writer has seen a marked
example. Occasionally an impulse in the epi-
gastrum is connected with an aneurism, either of
the aorta or of one of its branches. A pulsation
in this region has also been attributed to regur-

gitation of blood from the right auricle into the inferior vena cava and hepatic vein, in cases of tricuspid incompetency. A murmur may sometimes be heard in the epigastrium. Usually this is a conducted cardiac murmur, but occasionally it depends on an aneurism.

EPILEPSY (ἐπιλαμβάνω, I seize upon).—*Ætym.*: *Morbus convulsivus, sacer, major, &c.*; *Fr. Epilepsie, haut mal, &c.*, *Ger. Fallucht*.

DEFINITION.—An apyretic nervous affection, characterised by seizures of loss of consciousness, with tonic or clonic convulsions.

Of these two features—muscular spasms and loss of consciousness, neither is alone sufficient to establish the existence of epilepsy. Still, each of these two kinds of symptoms, when occurring in the form of an attack, is an *epileptic form* manifestation, as we find that patients who generally have convulsions only, are sometimes simultaneously seized with unconsciousness, and *vice versa* that in those very rare cases in which patients are attacked only with loss of consciousness, without any marked spasmodic action of any muscle, there are sometimes complete fits of epilepsy. The relationship between the two essential characteristics of epilepsy was well exemplified in the cases of two patients who were placed under the writer's care in London in 1860 by his lamented friend, Dr. W. Baly. These patients, who were brother and sister, were both incompletely epileptic: one had only attacks of convulsions, the other only attacks of loss of consciousness. Their father had been completely epileptic, and one of these two young patients had inherited one aspect of the disease, the other the other aspect.

Efforts in two absolutely opposite directions have been made to modify the significance of the word *Epilepsy*. Some writers give that name only to the special affection which others call *Idiopathic Epilepsy*. Other physicians have considered as belonging to epilepsy, most if not all of the non-febrile affections consisting in attacks of aphasia, of amaurosis, of paralysis, &c. or of disordered involuntary movements (choreic, tremulous, rotatory, &c.) There is no doubt that all apyretic nervous affections, appearing in seizures, have in that feature a common link with epilepsy, and it would be important to have a name for that group of paroxysmal neuroses. But the word *epilepsy* must remain for the special morbid manifestations that we have mentioned. As regards the application of the word *epilepsy* to those cases only in which no organic disease either of the nervous centres or other organs can be looked upon as a cause of that convulsive affection, neither the symptoms, nor the prognosis, nor the principal rules of treatment, show that we must entirely separate the idiopathic from the other kinds of epilepsy. It is, however, important, as will be shown hereafter, to try to find out, in every case of epilepsy, whether this convulsive affection is of the kind we call idiopathic, or proceeds from a peripheric or central organic lesion or irritation, or from some alteration of the blood.

ÆTIOLOGY.—Under this head it is only ne-

cessary to give an idea of the state of the nervous system that seems to exist in epilepsy. As early as 1857, the writer, in his work on this affection, showed that it essentially consists in an increased excitability of certain parts of the nervous system. This augmentation of excitability may exist only in the cerebro-spinal centres, or partly there and partly also in some peripheric parts of the nervous system. The analysis of phenomena when epilepsy is gradually produced, in animals leads forcibly to that view. We find in these animals, that, after a few days have passed from the time of the lesion which causes epilepsy (either a section of the sciatic nerve or of a lateral half of the spinal cord, in the dorsal region), the first change manifested consists in an increase of the reflex power of certain parts of the skin of the face and neck, while a greater excitability takes place in the medulla oblongata, in the upper part of the cervical region of the spinal cord, and in some parts of the trigeminal and of the two or three first cervical nerves. Gradually the reflex excitability of the nerve-cells in direct communication with the fibres of the nerves we have named increases, so that the irritation of the skin of the face and neck, instead of producing only, as at first, a reflex contraction of the neighbouring muscles, causes a tonic spasm of all the muscles of the trunk, neck and head, on the side of the lesion and of the irritation. Later on the reflex spasmodic action extends to the other side, and at last a complete attack of epilepsy (a month or later after the traumatic injury which acts as a cause) supervenes, characterised, as in man, by loss of consciousness, with tonic or clonic convulsions. In cases of injury to certain parts of the base of the brain in some animals, the same changes may take place but with two differences: 1st, the rapidity of increase in the reflex excitability of the parts above-named is very much greater than after an injury to the spinal cord or to the sciatic nerve. 2ndly, the zone of skin that acquires the power, when irritated, to give rise to an attack, is on the opposite side to that of the brain-injury, while it is on the corresponding side to that of the lesion of a nerve or of the spinal cord.

Want of space prevents the writer from giving the many reasons which show that what takes place in animals rendered epileptic by the lesions mentioned, applies in a great measure to the production of epilepsy in man. It will suffice to state that there are abundant facts which tend to establish the conclusion that in all nervous affections in which there are seizures, attacks, or fits of any kind, the essential feature is a morbid increase of the reflex excitability, while the differences between the various symptomatic manifestations depend on what nerve-cells are altered in their vital properties. In other words, we would say that, although there is the same morbid change, there are epileptic form, choreic, amaurotic, paralytic, aphasic phenomena, according to the particular nerve-cells in which that change takes place.

Nothing has resulted from the efforts that have been made to establish the theory that epilepsy depends on disease in any part having a special name in the nervous centres. The so-called *seat of epilepsy* has been successively placed in the cere-

bellum, the cornu ammonis, the pons Varolii, the medulla oblongata, the convolutions of the brain, &c. There is just as much reason to place that seat in those parts, as there would be to place it in the mucous membrane of the bowels or in the sole of the foot, or in any peripheric part of the nervous system, where an irritation is found causing epilepsy. In cases such as these last, as well as in the preceding, the very same things occur, an irritation starts from the place where we find an organic lesion, and proceeds to nerve-cells in the base of the brain and in the upper part of the cord (or in one of those parts alone). Through this irritation those nerve-cells have their nutrition altered, and after a time they acquire that morbid excitability which is the essence of epilepsy. We do not think it will ever be possible to recognise what cells are altered, as it is quite likely that the change in them is more dynamical than physical, and that no more microscopical differences could be detected between two of them, one normal and the other possessing great morbid reflex power, than there are visible differences between two pieces of magnet—one poor, the other rich in magnetic power.

The true seat of epilepsy therefore is in nerve-cells, having the power of producing morbid reflex muscular contractions, but the location of these cells must be variable, as is shown by the fact that the first symptom of an attack may be in the most different parts of the body. That these cells are located chiefly in the base of the brain is a conclusion borne out by many facts. But as we have ascertained, experiments on animals show that the very same kind of epileptiform convulsions can take place after an irritation of the skin, whether the nervous system is left entire or diminished notably by the ablation of the brain and cerebellum, and also of the pons Varolii and part at least of the medulla oblongata. The spinal cord has therefore a share in the production of epileptiform convulsions, and as we know that it can, in man as well as in animals, arrest the activity of the brain under some stimulation, we may easily admit that it may help in producing in man an arrest of cerebral activity during a fit of epilepsy.

ETIOLOGY.—*Heredity* deserves to be noticed first in this respect, not because it is the most frequent, but because it is a most undoubted cause. If we canvass what has been said by many writers on the subject of the heredity of epilepsy, we find that most statistics published do not give sufficient details to enable us to ascertain what are the morbid states of the brain in a parent which can cause epilepsy in the offspring. Pritchard has justly shown that all neuroses have the greatest relationship one to another. It is but natural, therefore, that epileptics are very often found to have had a father or a mother attacked with some nervous disorder. Moreau has shown that epileptics often have insane persons as their parents. If we put together those three groups of affections—organic disease of the brain, neuroses, and insanity—we find that epilepsy will often exist in the offspring of people who have been attacked with an affection belonging to one of those three groups.

As regards the influence of sex, we believe that

there is a marked difference among women and men of somewhat advanced age, the proportion of women being larger than that of men; but this is not the case, and it is even in some degree the reverse, for people under twenty-five years of age.

Age has certainly, independently of sex, a decided influence on the appearance of epilepsy. The following table given by Hasse is important, as it is the most extensive. It agrees fully with the results of the writer's own observation:

Age at commencement	No. attacked
Congenital	87
Under 1 year of age	25
From 2 to 10	281
" 10 " 20	364
" 20 " 30	111
" 30 " 40	69
" 40 " 50	51
" 50 " 60	13
" 60 " 70	4
	<hr/> 995

It is difficult to say at what age hereditary epilepsy is most prone to make its appearance. The writer's experience seems to show that it is between ten and twelve in boys as well as in girls. It is certainly by far more frequent to find that inheritance manifests itself before than during the period of change that puberty causes. Romberg, Dr. Russell Reynolds, and several other writers have already pointed out that such is the general rule.

Is puberty itself a cause of epilepsy? This is clearly proved by the large number of epileptics who, as shown in the preceding table, have been attacked between the ages of ten and twenty (364 out of 995).

Of other causes the most powerful are not those usually stated. In patients under fifteen years of age the most frequent cause after heredity is some more or less obscure alteration of nutrition of the brain, or congestion of that organ or of its membranes, remaining a more or less considerable time after typhoid fever or scarlatina. It is frequent, indeed, that in examining such patients (even when there are reasons to believe in heredity), there are a number of symptoms showing some deficiency in the action of the brain, as regards its motor, sensitive, or sensorial functions. It is most important to detect those symptoms (and they are so slight generally that they would not be noticed if not most carefully looked for), as the form of epilepsy, due to or allied with the cerebral alteration which then exists, is often curable, or at least can be considerably benefited by treatment.

Of the different etiological factors we have mentioned—heredity, age, puberty, sex, fevers—none but heredity can be looked upon as a real and direct cause of the form of epilepsy which is called idiopathic. The other factors only give origin to predisposing conditions; excepting fevers, which can do more, as they may cause diathetic, sympathetic, or symptomatic epilepsy.

Purely *psychical* and *emotional* causes seem to be by far less frequent than has been supposed. They act chiefly, if not only, as means of bring-

ing on attacks in persons more or less ready to have them.

If idiopathic epilepsy be set aside, we find that the etiology of the other forms of that affection is much more easily found out, and that almost always the cause is some recognisable irritation of a part of the nervous system. Disunion or injury of any part of the trunk and limbs or of the viscera; diseases or injury of any part of the cerebro-spinal centres or of their meninges, often produce epilepsy. The mucous membrane of the bowels and the cerebral meninges are the parts most capable of giving rise, not only to simple convulsions, but also to sympathetic epilepsy. Among the various organs constituting the encephalon, those having the greatest power of giving rise to symptomatic epilepsy are the optic thalami and the convolutions, especially those of the parietal lobes. But it would be quite wrong to conclude from the facts recently discovered by Fritsch and Hitzig, in their experiments on dogs and other animals, that certain parts of the cortex cerebri, near the fissure of Rolando, are much more connected with epilepsy than any other. The truth is that that neurosis can be caused by a disease of, or an injury to, any part of the cerebro-spinal centres: the anterior, the posterior, as well as the middle lobes, the base of the brain as well as the cerebellum or the spinal cord.

Sympathetic epilepsy is very frequently due to an irritation of the sexual organs, especially brought on by masturbation. In Anglo-Saxon countries, where children of the two sexes are less watched and less warned against the dangers of that fatal habit than in other civilised countries, epilepsy due to that cause is particularly frequent.

Alterations of blood, in quantity or quality, are certainly favourable circumstances, if nothing more, in the production of epilepsy. As regards the experiments of Kussmaul and Tunner, we will say that although a rapid and considerable loss of blood can cause an epileptiform attack, it has not been shown that such a cause has produced epilepsy. It is nevertheless true that anemia is a very frequent factor in the causation of epilepsy or any other neurosis. A weak and slow action of the heart also is found in a number of cases to be among the causes of epilepsy. But the reverse is sometimes observed; and we have not rarely seen cases of epilepsy in which the pulse was strong and beating more than 100 times a minute, without any disease of the heart or of any other organ, that could account for this great activity of circulation. In these cases the only morbid condition that could be looked upon as a cause of epilepsy was the abnormal circulation. In a case of this kind, placed under the writer's care by Sir Thomas Watson, the patient was rapidly benefited by treatment, and has had no more attacks since 1863, so that that kind of epilepsy is sometimes curable, as is the form due to anemia.

Whether epilepsy due to syphilis or to Bright's disease, or to affections of the liver, is ever produced in a direct way, and exclusively by some alteration of the blood, is not yet established, but it is certain that, especially where there exists one of the two last causes just mentioned, the

state of that fluid has a notable share in the production of the neurosis. But other etiological factors then exist: an irritation of the nerves of the kidneys, or of the liver, or of the meninges, and some alteration of structure of blood-vessels or of other parts of the brain, or sometimes a morbid deposit in the encephalon, or its membranes.

SYMPTOMS.—We shall consider this part of the subject under three heads:—the *premonitory*, the *paroxysmal*, and the *inter-paroxysmal* symptoms.

1 *Premonitory*.—The frequency of premonitory symptoms, according to the writer's experience, is much greater than is generally known. It is extremely important to find out the existence of these warnings, as in many cases attacks may easily be prevented if we know when they are on the point of taking place. When we say that premonitory indications are extremely frequent, we do not mean that the classic or *Galenic aura* is often found. That vague, queer, and unexplained sensation, whether accompanied or not by a muscular contraction, is certainly more frequent than is admitted, but is by far less often observed than the other kinds of warnings. Among the premonitory symptoms, there are four oftener observed than others:—one is a change of temper (irascibility appearing or increasing); another is a vascular contraction in the feet or hands, producing a diminution of temperature, and the two others a spasmodic state of some muscle, or an optical illusion or hallucination. It is impossible to sum up the various manifestations which indicate that an epileptic attack is forthcoming. Alterations of the various functions of the brain, sensations of all kinds, headache or backache, vertigo, sensorial disturbances, sleeplessness or sleepiness, palpitation, dilatation or contraction of blood-vessels anywhere, altered breathing, diminution or increase of the various secretions (of the skin, mucous membranes, or of the visceral glands), hemorrhages from the nostrils or other parts, fever, more or less marked weakness (general or local), hunger or thirst, disgust for food or drinks, sexual appetite or the diminution or loss of sexual desire or power, erection of the penis, spasm of the bladder, sometimes with involuntary evacuations of urine, involuntary expulsion of feces, cramps, trembling, choreic movements, tendency to run forwards, backwards, or round, rigidity or convulsions of a limb or other parts, paralysis of a limb or other parts, etc.,—such is an abbreviated list of the forerunners which have been noticed by a number of observers, and all of which we have seen, or have been found in our patients.

Sometimes one or several of these symptoms will appear a day or two before the attack, but generally the warning shows itself a few hours, or a very much shorter time (even only a few seconds or a minute or two) before the seizure. In cases of epilepsy due to organic cerebral disease, or to cerebral congestion (much more rarely in other cases), there occurs rather frequently, either during the attack or before it, drawing of the head towards one shoulder. If this occur before the loss of consciousness it is a most valuable warning, as it is then almost always possible to produce an abortion of the

attack. Premonitory symptoms unfortunately are sometimes deceptive, as they may appear more or less frequently without being followed by the attack; and in cases in which warnings usually precede the seizures, there are sometimes attacks without any forerunner.

2. *Paroxysmal*.—As regards the paroxysmal symptoms, they vary considerably according to the kind of attack. If the attack is one of *petit-mal* (*epilepsia minor*), there may be no other symptom than a loss of consciousness, with either a fixed state of the muscles of the eye, or a slight contraction of one or more muscles of the face or neck, or a movement of the lips, tongue, and throat, as in the act of swallowing. If we spoke according to our personal observation, we should affirm that an attack of *petit-mal* never consists in a loss of consciousness only, without the least trace of any other trouble whatsoever.

CAUSES.

1. Excitation of certain parts of the excitomotor organs of the nervous centre.

2. Contraction of the facial blood-vessels.

3. Contraction of the blood-vessels of the cerebral lobes.

4. Extension of the excitation in the excitomotor organs of the nervous centre.

5. Tonic contraction of some respiratory and vocal muscles.

6. Further extension of the excitation in the excitomotor organs.

7. Loss of consciousness alone, or with tonic spasm in trunk and limbs.

8. Laryngismus, trachelismus, and rigid spasm of some respiratory muscles.

9. Insufficient breathing; rapid consumption of oxygen, and detention of venous blood in the encephalon.

10. Asphyxia and perhaps pressure by accumulated venous blood in the base of the brain.

11. Exhaustion of the nervous power generally, and of the reflex excitability especially, return of regular respiratory movements.

Space does not permit of our insisting on the explanations given in this table. We will only say that the loss of consciousness is too rapid, too complete, to be due only or chiefly to a contraction of the blood-vessels of the cerebral lobes. In that case, as well as in cases of loss of perception and volition from a hæmorrhage, a softening, or some other disease of the brain, it is owing to an inhibition of the activity of cerebral nerve-cells that this symptom appears.

We will add to the above-given list of symptoms that besides the sudden loss of consciousness, with tonic spasm of the muscles of the eye, face, neck, chest, and limbs, and the uttering of a loud cry, which we observe in the beginning of a complete attack of epilepsy, there is sometimes biting of the tongue or lips. After the first stage, which is usually extremely short (not lasting generally more than from 10 to 20 seconds), general clonic convulsions appear, the face becomes more or less violet or purple, the tempera-

Dr. Russell Reynolds, however, states that he has seen such attacks, and therefore we must admit that sometimes a pure and simple loss of perception and volition is all that exists in a seizure of epilepsy minor. In such an attack the patient may, if walking, continue to walk, but if talking, he stops—generally for so short a time, however, that the trouble may pass absolutely unnoticed by listeners. Usually an attack of that kind lasts only from one to four or more seconds.

An attack of complete epilepsy (*epilepsia major*) is a very complex series of phenomena. Years ago (in 1857) the writer gave the following table, which shows at the same time in what order and by what mechanism the symptoms appear. Only on a few points has he to alter the views held twenty years ago. It will be seen that in this table the effects successively produced become causes in their turn.

EFFECTS.

1. Contraction of blood-vessels of the brain and face, tonic spasm of muscles of the eye and face.

2. Facial paleness.

3. Loss of consciousness; congestion in the base of the brain and the spinal cord.

4. Tonic contraction of the laryngeal, the cervical, and some respiratory muscles (laryngismus and trachelismus).

5. Epileptic cry.

6. Tonic contraction reaching most muscles of trunk and limbs.

7. Fall or precipitation, forward or backward, to the ground.

8. Insufficient breathing; obstacle to entrance of blood into the chest, and to its issue from the cranio-spinal cavity.

9. Increasing asphyxia.

10. Clonic convulsions everywhere; contractions of the bowels, the bladder, the womb; increase of secretions; efforts to inspire.

11. Cessation of the fit; coma or fatigue; head ache, and sleep.

ture of the body rises, the skin becomes covered with perspiration, and saliva, reddened by blood or not, flows out of the mouth.

After the cessation of the convulsions, the patient is often so exhausted that the limbs fall, if lifted up, as if they were quite paralyzed; the respiration is stertorous; and the heart beats with great force and rapidity. If care be not taken to have the tongue brought forward, and if the head be not placed on one side, the heavy breathing and the comatose state which often exist, continue for a long time. Even if care be taken about the position of the tongue, these disturbed states of the brain and breathing may last an hour or longer, in very bad cases. In some epileptics who have a series of fits in rapid succession, there is a more or less prolonged period of coma after each attack. Sometimes in such cases death terminates the scene after a more or less considerable number of attacks.

On waking up either from the coma or the

sleep following an attack, most patients are very tired; their limbs and trunk aching as well as their head. Usually there is some mental alteration, often consisting of confusion or stupor, and sometimes delirium. The mind, however, may be quite clear, even after a violent attack, and the head free from pain, the only effect of the fit being general lassitude. On the contrary, after an apparently slight seizure there is sometimes considerable mental disorder. The degree and duration of stupor after an attack have no relation to the duration of the convulsive period. Stupor is an effect of asphyxia and is, therefore, in direct relation with laryngismus, tracheismus, and the spasms of the thoracic muscles, of the diaphragm, and perhaps of the bronchial tubes also. It has been stated and denied that the urine passed after an attack of epilepsy sometimes contains albumen, in patients free from kidney-disease. In at least two cases the writer has ascertained that there was a notable amount of albumen in the first issue of urine after attacks in which there had been violent spasmodic contractions of the abdominal and thoracic muscles. These two patients afforded no evidence of disease of the kidneys or of the heart.

Attacks of epilepsy are sometimes very slight, consisting only, besides the loss of consciousness, of an extremely short tonic spasm of muscles of the trunk, the neck, the head, and the limbs. But even in the shortest and slightest attack of that kind the epileptic cry may be uttered and the tongue may be bitten.

The symptoms of a seizure of epilepsy *mitior* (*petit-mal*) are very different from those of a violently convulsive attack of epilepsy (*grand-mal*). The loss of consciousness occurs only for one or a few seconds, and the spasmodic contractions take place in a few muscles only, in the face, tongue, throat, eyes, and neck. If seized while standing up the patient very rarely falls, and on the contrary, if walking, he may continue his movement as regularly as before the fit. If attacked while speaking, he stops while the consciousness is lost, and on recovering it he may complete the unfinished sentence, so that the bystanders may know nothing of what has occurred. Sometimes, however, the patient's mind is deeply altered, even when the attack of *petit-mal* has been as short and slight as possible.

Nocturnal attacks of epilepsy may occur without any knowledge of their having taken place. Indeed, the writer has sometimes been consulted by persons who only asked for advice on account of headaches, and who had no pain in the head except after nocturnal attacks of epilepsy occurring without their knowledge. In such cases the patient, after a seizure during sleep, wakes up tired, as if he had walked considerably; he has pains in the limbs, the back, and the head. He finds his mind confused, and his memory affected; he feels disinclined to get out of bed or to exert himself in any way; and he often is excitable or depressed. Sometimes his tongue or his lips are sore, and if the pillow is examined it shows bloody spots. More rarely it is found that an involuntary evacuation of urine has soiled the bed. Anyone sleeping within hearing distance of the patient may be awakened by the piercing epileptic cry, and then hear the noise

of the shaking of the bed caused by the convulsive movements. Such attacks, although very frequent and also very violent, may remain altogether unknown and unsuspected by the patient and his friends.

3 *Inter-paroxysmal*.—The general health of epileptics is usually very poor. Besides the alterations of their mental powers and especially of their memory, they show a great deal of excitability and often depression of spirits. Their circulation and their digestion are often affected. There is nothing special to them, however, either in the morbid state of their mind and of their feelings, or in the disturbances of their physical health. We do not consider the mental aberrations observed in the inter-paroxysmal state as elements in the symptomatology of epilepsy. These aberrations can exist without epilepsy, and in a great majority of cases epilepsy is unaccompanied by them.

The frequency of attacks varies immensely in epilepsy. In one case the writer learned that for more than a century years the patient had passed no night without a fit, and for more than a century years the average nightly number of fits had been about twelve, which gives a total of more than forty thousand attacks in ten years. On the other hand, he was once consulted by a patient, sixty-two years old, who has had but seven attacks since the first occurred, forty-three years ago, the interval between that and the second fit having been thirteen years, and the interval between the two last seizures having been seven years. Between extremely different cases like the two just mentioned, we find the greatest variety as regards the frequency of attacks. Usually, however, there are a number of fits every month. If there are attacks with extremely violent convulsions, the frequency is generally much less than when the convulsions are slight. Seizures of *petit-mal* are usually very frequent. A perfect periodicity is extremely rare, but an approximation to periodicity is not rare, especially in women. Singular and inexplicable periods will sometimes exist; the writer knows of a number of cases with a weekly periodicity, and of a case in which for years attacks occurred every forty-nine days.

DIAGNOSIS.—In most cases it is easy to distinguish epilepsy from the few affections which resemble it. Sometimes, however, difficulties exist. There is no essential difference between the attacks of eclampsia in women and children and attacks of epilepsy, except the existence in eclampsia of a periphere cause of irritation, which is likely to disappear. But those purely reflex epileptiform attacks of women and children are sometimes succeeded by genuine attacks of epilepsy, changes in the nervous centres occurring during the eclamptic attacks, which lay the foundation of persistent epilepsy, showing itself after the periphere irritation, which was the first cause, has ceased to exist. It is sometimes, therefore, almost impossible, in children especially, to say if we have to deal with eclampsia or epilepsy. The same may be said of all kinds of attacks of loss of consciousness and convulsions due to a periphere cause, whether we call the affection eclampsia or reflex epilepsy. (See CONVULSIONS.) The first cause in these cases may

comes to exist without our discovering positively that it has disappeared, and still attacks may continue. As the treatment is to be very much the same, except that in purely reflex epilepsy we have to fight against the peripheric cause besides making use of means against epilepsy itself, a mistake is not dangerous.

Hysteria sometimes borders on epilepsy, so much so that we must accept for certain groups of nervous symptoms, the name of hysterio-epilepsy. Usually, however, there is no complete loss of consciousness in hysteria: there is rather a disordered consciousness. The convulsions generally do not follow the ordinary cycle of those of epilepsy: they are not merely tonic first and then clonic; they often are alternately, and many times successively, clonic and tonic. They sometimes resemble voluntary movements rapidly executed. The attack is not followed by the stupor that follows so often a fit of epilepsy. Before and after the attack, the patient exhibits (or has done so) purely hysterical symptoms. Usually, pressure on the ovary during the attack stops or increases it, while nothing of the kind is found in a fit of epilepsy, except, of course, one of hysterio-epilepsy, in which case the two affections are blended in one.

Epilepsia minor (*petit-mal*) sometimes cannot be easily distinguished from syncopal attacks. Usually, however, the pulse does not lose so much in frequency and force in *petit-mal* as it does in fainting. The loss of consciousness lasts for a shorter period in *petit-mal* than in syncope.

Between idiopathic epilepsy and cerebral epilepsy, there are generally very marked differences. In epilepsy due to disease of the brain, attacks are almost always preceded by an aura, consisting either in referred sensations or in cramps; in such attacks, convulsions often occur without loss of consciousness, very frequently the convulsions are unilateral, either on the paralysed side or on the other side, and almost invariably, if they are not clearly unilateral, differences in intensity, in kind, and in duration exist as regards the spasmodic contractions between the two sides of the body.

PROGNOSIS.—Inherited epilepsy is very rarely cured. The writer can positively state, however, that it may be cured. Among other good cases of persistent cure, he has seen two extremely remarkable. The patients were first cousins, and had inherited the disease from a grandmother: one of them died from a fall while intoxicated, five years after his last attack of epilepsy; the other died in China, from typhoid fever, seven years after his last attack. They had both been treated for about two years, in 1852 and 1853.

There is a very great difference as regards prognosis between pure idiopathic epilepsy and other forms of that neurosis. The chances of cure, although never great, are by far greater when some curable or amendable organic alteration exists, as a cause of epilepsy, than when no such thing exists. One form of this nervous affection—that which is due to some congestion or even a more serious alteration of the brain,—consecutive to typhoid fever, scarlatina, or measles, is very often much benefited by treat-

ment, if not cured. Epilepsy caused by disease of the brain—syphilitic or not—is much more curable than any other form of that neurosis. Epilepsy beginning in childhood, from teething or a bowel-complaint, and having lasted many years, is almost incurable.

COMPLICATIONS AND SEQUELÆ.—Epilepsy has no necessary or usual complication. The diseases which accompany it often are frequently its causes and not complications. Bright's disease and other organic affections of the kidney, diseases of the liver, the womb, and other viscera, when allied with epilepsy, if they have not been the first and only cause of it, are powerful additional causes. There are no sequelæ of epilepsy worth mentioning except some amaurosis, which we invariably find in patients cured of that affection, after having suffered from it for many years.

TREATMENT.—A most important fact ought at first to be pointed out under this head: it is that as every attack causes in the nervous centres changes which prepare other attacks, it is essential to produce, if possible, the abortion of attacks whenever warnings occur. The treatment to obtain such an abortion varies with the kind of warning. In cases in which a real aura exists many means can be employed with the greatest benefit. The writer long since showed that the old-fashioned mode of prevention of attacks, consisting in the application of a ligature round a limb, acts not as the Galenic doctrine supposed that it did, that is, by barring the way to something going up to the brain, but, on the contrary, in doing just the reverse, that is, by sending an irritation towards or rather to the nervous centres. The writer has also shown that the ligature need not be left applied, and that a greater success is obtained by tying suddenly and very quickly a handkerchief or a band, and repeating this tying several times in succession, than by applying the ligature even very tightly and leaving it so. He has also demonstrated—1st That the ligature can do good even when applied on another limb than that where the aura is felt, although it is usually more efficacious on the latter, and 2nd. That pinching or striking the skin, or irritating its nerves by heat, by cold, by galvanism, or by repeated pricks with a needle, will generally do as much good as the ligature.

In those cases in which an involuntary muscular contraction takes place before an attack—that is before the loss of consciousness—one of the most efficient means to produce an abortion of the fit is to draw forcibly on the contracted muscles, so as to elongate them. For instance, in those cases in which the unconsciousness is preceded by a contraction of the muscles of the neck, drawing the chin towards one shoulder, turning forcibly and rapidly the head towards the opposite shoulder, gives in most cases a very good chance of checking completely the tendency to the fit. In case of contraction of the flexor muscles of the forearm, forcible extension of the hand over the forearm may succeed in preventing the attack. A blow, pressure, or friction on parts where some muscles become rigid, may have the same favourable effect.

If there are disturbances of breathing among the premonitory symptoms, the inhalation of ether or chloroform may prove successful. In

cases of laryngismus similar means, or the cauterisation of the fauces by a strong solution of nitrate of silver has been found most useful by the writer. The use of anaesthetics as a means of warding off an attack is too much neglected. By the help of ether in inhalations we have succeeded, with Mr. R. Dunn, in preventing an attack in a patient who had had a fracture of the arm in a previous seizure, and who used to have a fit regularly every week. A whole week was gained in that way. In some cases the recurrence of attacks has been ward off by giving chloroform or ether (by inhalation) to patients who had had the first of what would have been otherwise a series of many fits. There is, in cases in which a fit is expected, a considerable chance of preventing it by etherisation or chloroformisation.

According to the kind of warning and to its next one means or another out of a very large number (only some of which we shall mention), ought to be used. An emetic, a purgative, a stimulant, the immersion of the two hands in hot water, the application of a lump of ice to the back of the neck or between the shoulder-blades, the subcutaneous injection of a solution of $\frac{1}{10}$ of a grain of atropine with $\frac{1}{4}$ of a grain of morphine, powdered *aurum* taken as snuff, a dose of 25 grains of hydrate of chloral, the inhalation of a small dose of nitrite of amyl, extremely rapid and ample voluntary respiratory movements for five or six minutes, jumping, running for at least ten minutes, reading very loud and fast—such are some of the means which we have found to be the most successful.

The second point of importance about treatment is to try to discover a part of the body which can by irritation give rise to a premonitory symptom of an attack, or even to an attack itself. If such a part is discovered, counter-irritation of some kind is to be applied there. Our remarks must be confined to saying, that hard pressure on certain parts of the head, the spine, the breast, the abdomen, or the limbs, has in a number of cases produced an attack or some symptoms of it. We have seen the passage of a galvanic current produce the same effect. In such cases a blister or other local application has done good in diminishing the violence or frequency of attacks, and even, in a few instances, helped notably to a cure.

The modes of treatment of epilepsia gravior or mitior which chiefly deserve to be noticed are the following:—

Against idiopathic epilepsy the most powerful means consists in the simultaneous use of some tonic remedy (such as strychnine or arsenic) in a solution to be taken after meals, and of a mixture composed more or less like the following:—

R Potassii iodidi, ʒij.
Potassii bromidi, ʒj.
Ammonii bromidi, ʒʒij.
Potassii bicarbonatis, ʒj.
Tinct. calumbæ f. ʒj.
Aque destillatæ f. ʒvj.

Of this solution may be given to adults four doses a day, three of one teaspoonful each before meals, and the fourth of three teaspoonfuls at bed-time with as much water as desired. According to many circumstances the dose of one

or another of the ingredients is to be changed. For example, if the *potit-mal* exists alone, or coexists with the complete epilepsy, the dose of the bromide of ammonium must be larger, and that of the other bromide diminished. If there is a weak pulse the sesquicarbonate of ammonia is to be substituted for the bicarbonate of potash. In the writer's work on functional nervous affections all the rules relating to that mixture are given, and we will only say now that its use is by far more beneficial than that of any of its ingredients alone or of two of them. Two essential rules are to be followed when either such a mixture or any of the many bromides is employed against epilepsy, the first is, that there ought to be no interruption whatever in the use of such remedies, as the whole benefit that may have been obtained may be lost at once after an interruption of even only a few days; the second is that the treatment must be persevered with for at least two years after the appearance of the last attack. There is no marked lull in the great majority of cases from a prolonged use of a mixture like the above, many patients have taken it for several years, and some for six, eight, or ten years without any marked bad effect.

Idiopathic epilepsy (either the complete or the incomplete, that is the *potit-mal*) has been successfully treated (very rarely cured, but often benefited) by the use of a number of remedies. Judging by his own experience, the writer names, as the most powerful, atropine and the ammoniated sulphate of copper. Although not able generally to produce as much and especially as prompt a good effect as the above mixture, these two remedies have the superiority over this mixture that they need not be constantly used, and that there is no necessity of continuing to employ them longer than eight or ten months after the last attack. Next in importance after the three means spoken of will come the coryledon umbilicus, the nitrate of silver, and zinc preparations, especially the bromide of zinc.

The other forms of epilepsy require pretty much the same modes of internal treatment, but, of course, according to the cause of each form some special means should be employed. In the above prescription the dose of the iodide of potassium must become as large as that of the bromide of potassium, when syphilis is considered to be the cause of epilepsy, and, if needed, mercury should be administered also. If epilepsy depends on some visceral affection it is clear that the treatment should be directed against that affection. But if the liver is diseased from some influence of malaria the sulphate of quinine should not be given, as it is almost always a bad remedy against epilepsy, often more hurtful than it can be useful. Arsenic then should be the remedy used against the sequelæ of fever and ague. If quinine must be employed in cases of clearly periodical epilepsy, the valerianate should be given rather than the sulphate.

It may seem strange that we do not name iron among the remedies against epilepsy. The writer's experience shows that in most cases iron is rather harmful than useful. It is only in cases of epilepsy allied with or caused by chlorosis or considerable anæmia that its good effect is often

very marked. Even then, we have sometimes found manganese more serviceable. There is, however, one salt of iron—the citrate—which, although less powerful against a deficiency of blood-globules, is however less apt to give rise to attacks than are most ferruginous preparations in a number of cases.

Of other internal remedies, cod liver oil if well borne is certainly useful, especially against the *petit-mal*. The importance of giving simultaneously with the bromides either arsenic or strychnine has been already mentioned. Arsenic alone can do much against any form of epilepsy, perhaps chiefly against *petit-mal*, but the writer does not personally know of a single case of cure by its use. Strychnine can also alone do good, but less than arsenic. Digitalis or digitaline have been credited as having effected cures; so have turpentine and a number of other medicines. The writer has obtained only a very limited good from the use of digitalis or turpentine. As regards the curative influence of the nitrate of amyli, it is yet *sub judice*.

From counter-irritation there is a great deal to be expected. Ice (not in a bag) the actual cautery, blisters, &c., applied to the back part of the neck and between the shoulder-blades, are most useful in any form of epilepsy, especially when there is a great deal of headache and considerable heat in the head. When attacks are very violent and frequent, there is some good, and at times a decided amelioration to be obtained from croton oil applications on a great part of the shaved head. Setons and issues very rarely do any good, and often weaken and irritate.

A circular blister round a limb, a finger or a toe, is most useful in cases of an aura starting from those parts. It is known that in such cases a nerve has been divided, sometimes with great success. Of more serious operations, there is one which ought to be completely rejected, unless there is good reason to suspect the existence of an intracranial aneurism on the carotid artery or one of its branches, namely, the ligation of that artery in the cervical region. Although beneficial in a few cases it is a dangerous operation, and much inferior to many other means of treatment. Trepanning the cranium, except on clear, rational ground, is certainly to be avoided, although it has in a few such cases cured or ameliorated the condition of the patient. But when the attacks are extremely violent and frequent, especially if they seem to endanger the life of the patient, and when there is a clear evidence of pressure exerted on the brain, that operation, which in such cases has often been useful, ought to be resorted to, after the failure of other means. Laryngotomy or tracheotomy are to be rejected, except in those instances in which the operation would have to be performed even if there were no epilepsy. In cases of laryngeal epilepsy the writer has found the cauterisation of the fauces and of the larynx itself with a strong solution of nitrate of silver a very useful means, and even in one case a means of complete and persistent cure.

During an attack of epilepsy, excepting what simple common sense suggests, there is very little to be done. Pressure on one or on both

carotid arteries, which we now know to act on account of the accompanying pressure on the par vagum and on the cervical sympathetic nerve, will sometimes considerably shorten an attack, especially if there is violent action of the heart. At the time convulsions cease, the tongue ought to be drawn forward and the head of the patient, if not his body, turned sideways, so as to avoid the covering of the larynx by the half-paralysed tongue. No other interference at all with the patient should be the rule after the attack.

C. E. BROWN-SÉQUARD.

EPILEPTIFORM } —Partaking of the
EPILEPTOID } characters of epilepsy, terms generally applied to convulsions. See CONVULSIONS.

EPILEPTIC INSANITY.—The different classifications of mental diseases agree generally in making a separate division of the intellectual derangement related to epilepsy. This latter ranks prominently among the predisposing causes of insanity, but has not been found to proceed from it, unless the epileptiform convulsions observed with the majority of mental affections be improperly regarded as epilepsy. Evidently, the fits of *petit mal* are associated with insanity more frequently than even the most violent of *grand mal*, however, from this association it does not necessarily follow as currently believed, that insanity should be a mere consecutive accident of the fit. Falret, endeavouring to reconcile the views on the subject put forward by French alienists, asserts that insanity chiefly occurs as a consequence of epileptic attacks recurring at short intervals after a prolonged suspension of the disease—which is very true. Yet, insanity may besides break out after nocturnal attacks, or seizures of *petit mal*, without any relation whatever to the length of their suspension or number; and mania—usually of the most furious character—may also appear as a forerunner instead of the sequel of the fit; or it may originate with the very first epileptic seizure and recur continually thereafter. Lastly, the existence of epilepsy and paralysis brings about, from the beginning a gradual though obvious impairment of the intellectual faculties, which becomes exacerbated by the fits, and terminates in dementia. No less open to objection is the kindred nature of the physical and psychical manifestations of epilepsy, admitted by Falret, to establish thereupon the *intellectual petit mal* and the *intellectual grand mal*. The first correspond with the incoherent and violent state described as furious mania. The second may continue from several hours to several days, constituting an intermediate condition between the irregularities of character which attend the fit, and the slightest disturbance of the furious manicular seizures. In the midst of this confusion of mind epileptics recall to their memory the painful past impressions, which spontaneously spring up in their imagination, always the same at every new access, and give themselves up to instantaneous, sudden acts of violence. After such fit of violence, the epileptic either quickly returns to himself, regaining his consciousness and rendering an imperfect account of his misdeeds, or, on the contrary, he escapes, running away in a

bewildered and greatly agitated condition. In either case the confusion, if not the complete oblivion of what has happened, is almost always a striking essential feature of this mental state, so much resembling the awakening from a dreadful dream. The foregoing phenomena are, indeed, exhibited by the insane epileptic; but the distinction between the *intellectual grand mal* and the *intellectual petit mal*, and their respective references to the physical paroxysms of epilepsy, supposed by Falret, implies an essential connection which is far from being constant. The most fearful fits of rage, or frenzy, may follow the *petit mal*, or may burst out without any visible attack at all, while nocturnal fits, or *petit mal* and *grand mal*, recurring separately or together, may often herald a harmless insanity with the highest degree of melancholia with stupor, without the least violent reaction— which, as set forth by Falret, should exclusively occur upon the physical *grand mal*. In other common instances, the epileptic, without any dejection or stupor, but excessively disposed to react violently on the slightest moral or physical irritation, talks and acts coherently, in an apparently rational manner, but actually without any appreciation whatever of his outward relations—a strange state that may occur along with diurnal or nocturnal fits, or irrespective of any manifest physical paroxysm, as the only exponent of the epileptic malady. For all these reasons, instead of attempting to establish an immediate relation of cause to effect—which cannot be proved—between the psychical and physical paroxysms, it is safer to regard epileptic insanity, or, using a more adequate term, *cerebral epilepsy* as one of the manifestations *per se* of the spasmodic neurosis, recognising its essential source, not in this or that kind of fits nor in their frequency, but in the very pathogenic elements of the disease. Unconsciousness, with an excessive reflex susceptibility, displays itself as the chief characteristic of cerebral epilepsy, capable of occurring either alone, or coupled with any other form of the epileptic malady, preceded sometimes by an *aura*, identical to that which may foretell other attacks.

DESCRIPTION.—Assuming the practical view above maintained, it is readily observed that epileptic insanity—like every other variety of insanity—manifests itself under an *intermittent*, a *remittent*, and a *continuous* form.

The *intermittent* form is characterized by periodical attacks, breaking out at irregular intervals, either before or after the fits, which moreover, often explode as though they were an intercurrent accident of the maniacal seizure. When this latter directly follows the *grand mal*, the patient instantly passes from the clonic stage of the fit into the maniacal, without any intermediate period of sleep or coma. The intermittent attacks of cerebral epilepsy rarely last less than two or three hours, they may be developed one or more days after instead of closely accompanying the fits, and ordinarily have then a longer duration; or, again, the intellectual disorder may reach its most dreadful stage without any spasmodic fit being seen or suspected. Morel proclaims that in these cases the occurrence of convulsions never fails to disclose

the true nature of the insanity, as such patients ultimately arrive at the convulsive fit and die. This, however, is too absolute a statement, for undoubted cases of cerebral epilepsy are frequently met with, without the supervision of any spasms in the final state of cerebral congestion, the patient sinking into a profound coma, but sometimes excreting automatically in this insensible state the same movement of the head, or some other habitual gesture. It is in intermittent cerebral epilepsy that unconsciousness appears most strikingly, although no reference has been hitherto made to its clinical or far-reaching medico-legal significance, nor to the explanation it furnishes to the strange objection or amnesia, so peculiar to epileptics after the commission of their criminal acts. Religious monomania and erotomania are common in the earliest stages of intermittent cerebral epilepsy. However the peculiar disposition to wander about in an aimless manner, the volubility and instantaneous changes characteristic of the deportment of individuals labouring under this stage may be transformed into an opposite manner of acting, the epileptic then remaining for hours or days entirely motionless and silent, with a sullen expression of countenance, in a physical and mental condition which almost verges on catalepsy, and involuntarily passing his urine and excrements, like those suffering from stupidity or *melancholia altiora*.

No complete recovery of intellectual soundness takes place between the paroxysms or maniacal exacerbations of *remittent* epileptic insanity. In the *continuous* form the mental trouble persists throughout, not essentially modified by the recurrence of the fits. In either instance dementia imbecility, or a range of symptoms very similar to those of general paresis, is more noticeable than the unconsciousness with high irritability and sudden violent acts observed in the intermittent cases. The remittent and continuous forms offer no embarrassment as to their diagnosis, and afford, upon close examination, the most typical examples of *folie circulaire*.

The intermittent cerebral epilepsy, which occurs in no proximate connection with any fit of *grand mal* or *petit mal*, corresponds to the *lurated epilepsy* of Morel, *intellectual epilepsy* of Maudsley, *psychical epilepsy* of Krafft-Hallng, and most of the cases of the so-called *destructive mania* (*manie sans delire*), and of *mania transitoria* also belong to this category. The main points to observe in this perplexing aspect of the spasmodic neurosis are the following—Cerebral epilepsy implies an advanced stage of the epileptic malady, but may and does nevertheless appear at any time throughout its progress, even when it has been developed in a sort of hidden or *lurated* manner. The discrimination between *lurated* epilepsy and other forms of intermittent mania is rendered easy by a reliable account of the antecedents of the patient. The demonstration of parents stained with any constitutional nervous disease, or addicted to intemperance, an extreme susceptibility to anger, with strange peculiarities of character, moral depravity, and a more or less dwarfed development of the intellectual faculties in addition to

the onset of fits during infancy, or adolescence, and subsequent vertigo or fainting fits or instantaneous absence and giddiness, are elements of diagnosis which evince the true epileptic nature of any transitory, instinctive, or mental disorder that has recurred without variation, or with such a complete resemblance to the preceding paroxysms as we notice but exceptionally in any other kind of mania. The attacks of cerebral epilepsy recur with the periodicity and similar premonitory symptoms peculiar to other epileptic paroxysms. When displayed from the beginning, as after traumatic injury to the head, syphilis, &c., they ordinarily recur at shorter intervals than otherwise. The manifestations of cerebral epilepsy are never solitary, they involve a repetition of fits of mental or physical character. Consequently, such insanity, as already advanced, discloses an active but not ultimate progress of the epileptic malady, and hence the possibility of its cure or relief. Epileptic insanity is rarely manifest before puberty, for idiocy accompanies congenital epilepsy in *idiotic epileptics*, and imbecility the epilepsy which develops itself during childhood in *epileptic imbeciles*. There is a clear relation between the intensity and length of the epileptic insanity and the impediment to the cerebral circulation, which in its extreme degrees may terminate in meningitis. Giddiness with perspiration of the head, sometimes very profuse, and epistaxis, are symptoms existing during or immediately after the paroxysms. The cerebral congestion is further betrayed by the bloated and livid appearance of the face, the injection of the conjunctivæ, with a thick white discharge collected in the angles of the eyelids, and the heavy look of the patient. The pupils during the exacerbations of the paroxysm—when the patient becomes boisterous and violent, exhibit a dilatation and contraction, like that which may last for several seconds or even a minute after the fits of *petit mal* or *grand mal*. Slowness of the respiratory activity, with marked loss of its normal relation to the pulse, is regularly detected in every case where the *epileptic habit* has become well established, as also an increased temperature of the skin before the explosion of the attack, ordinarily attended with incontinence of urine when it takes place during sleep in nocturnal epilepsy. There is always at the close of the fit of epileptic insanity a period of sleep, which effects the transition to a sound condition of mind. This sleep may be prolonged several hours, accompanied by a heavy breathing or snoring, which makes it easily mistaken for the sleep of drunkenness, a mistake strongly counterpoised by the quick recovery of the patient. Another conspicuous sign of epileptic insanity is the *epileptic echo*, or repetition by the patient of the same word or phrase addressed to him, or present in his mind. Romberg has described the *echo sign* as indicative of softening in cerebral diseases, but in epilepsy it chiefly evinces a perverted will. The phenomenon renders itself very evident in the writings of the epileptic insane, even during the very occurrence of the fit, thus affording confirmation of the automatic repetition of motory and intellectual acts so peculiar to epilepsy.

Morbid sensorial phenomena of various kinds existed in 86 per cent. of 267 cases of epileptic insanity. Hallucinations of hearing were recorded in 63 per cent. of the said number; of sight in 53 per cent.; of hearing and sight in 43 per cent.; of smell in 6 per cent.; and finally about 30 per cent. of the cases showed some disturbance of general sensibility, such as anæsthesia, hyperæsthesia, &c. If we take into account the almost constant occurrence of some of these morbid sensations, and the hyperæsthetic condition attending epileptic insanity, it will not be difficult to realise the manner in which its victims are fascinated by the feelings they experience, which ordinarily assume the most frightful and deceitful character. Whenever we have data for comparison, we shall see that the hallucinations of hearing are the most frequent, as shown by the foregoing statistics. Morel has, with great propriety, insisted on the unmistakable character of these hallucinations of hearing, and the piercing sudden noises, usually heard by epileptics, differing entirely from the noises complained of by those labouring under the delirium of persecutions, which always lead an attentive observer to a definite diagnosis of cerebral epilepsy.

The intellectual aura, which like precursory clouds of a threatening storm may anticipate the outbreak of a fit of cerebral epilepsy, is an accessory symptom common to all the attacks, already noticed in the general description. In regard to the moral and intellectual changes which characterise epilepsy, and may be superinduced from its very onset, effacing—as Maudsley says—the moral sense as it effaces the memory, there is one brief remark to be made. Such moral depravity is more apt to occur from the very inception of the attacks, when epilepsy is induced by a traumatic injury to the head; its appreciation is beset with difficulties, and although these morbid dispositions do not constitute a state of insanity, they must place the epileptic—as justly declared by Baillarger—beyond the common rule, and entitulate at least his legal responsibility.

LEGAL RELATIONS.—Bearing in mind the reflex nature of the physical and mental phenomena inherent in epilepsy, and our inability to avoid the effects of reflex actions, it follows as a matter of course that epileptics should be regarded irresponsible for any criminal act they might commit under the influence of a paroxysm. Those familiar with epileptics know that the majority have no knowledge, or at least a very imperfect idea, of their misdeeds, such state of unconsciousness being the chief characteristic of epileptic insanity generally. This unconscious cerebration exhibits itself in a high degree in epilepsy, but is not peculiar to it, for we observe it more or less in all forms of insanity, and notably in somnambulism. Finally, a clear demonstration of the above-described phenomena is indispensable before we can fully appreciate or decide upon the nature of any act perpetrated during an alleged condition of epilepsy.

The reasons here briefly presented for the irresponsibility of confirmed epileptics prove no less forcibly that society, in its turn, must be protected from their misdeeds, since they are unquestionably the most dangerous class of individuals. Therefore criminal epileptics should

never be allowed to go at large until sufficient time has elapsed to demonstrate the arrest of their malady, upon continued observation by a competent physician.

TREATMENT.—The treatment of epileptic insanity does not differ from that of epilepsy generally (see EPILEPSY). Let it be simply noticed that ergotine in doses of three to six grains, and enococ conii in doses of three drachms to one ounce, in often repeated doses, with counter-irritation to the lower part of the neck (seton or caustery), and cold shower-baths or packing, are among the most reliable means to be resorted to, to abate or prevent the great excitement of the insane epileptic. M. G. ECHAVEZIA.

EPIPHORA (*ἐπι, upon, and φέρω, I carry*). A flow of tears, so persistent that they run down the cheek, due either to obstruction of the lachrymal duct or to excessive secretion. See LACHRYMAL APPARATUS, DISEASES OF.

EPIPHYTA (*ἐπι, upon, and φυτόν, a plant*). These are the plant-like organisms found on the skin, and its appendages or on mucous surfaces, the so-called *vegetable-parasites*, originating certain diseases, such as the various forms of tinea and thrush. The more important of them are the Achorion, Trichophyton, and Microsporum. The achorion Schoenleinii is the vegetable fungus which constitutes the mass of the crusta of favus, and belongs to the group of Oidie. The trichophyton is the dermatophyte of tinea and syccosis, and is found in the substance of the hair as well as in the epidermis. The microsporum, termed Epidermophyton by Kuhn, is the parasitic fungus of phytosis versicolor. Both the latter are members of the group of Torulaceæ. See EPIPHYTIC SKIN-DISEASES, and APHTHÆ. ERASMUS WILSON.

EPIPHYTIC SKIN-DISEASES.—**SYNONYMS:** Vegetable parasitic skin-diseases, *Tinea*; Dermatophytic diseases.

DEFINITION.—Epiphytic diseases are diseases due to the attack upon the integuments of parasitic fungi.

DESCRIPTION.—Speaking generally it may be said that an epiphytic disease consists of three component elements—(a) a soil favourable to the growth of the attacking epiphyte, (b) the growing epiphyte itself; and (c) the effects produced upon the skin-tissues by the development and increase amongst them of the epiphyte.

Epiphyte Soil.—As regards the soil it is difficult to exactly describe it, but it is indispensible that the young, those who are assimilation is at fault, the lymphatic, and fair children, furnish a soil peculiarly favourable to the growth of vegetable parasites.

The Epiphyte.—The epiphyte itself consists of reproductive cellular bodies called *conidia* or sometimes spores formed of an outer envelope composed of cellulose, and an inner membrane or utricle, enclosing granules floating in a liquid, and mycelial filaments. The spores are round (as in *tinea tonsurans*) or oval (as in *favus*), having an average diameter of .006 mm., and furnished in most cases with a nucleus. These conidia are double-contoured, solitary, or arranged in rows, or massed in groups (*tinea versicolor*). The mycelial threads vary somewhat in appearance; they may be fine transparent filaments, or

large distinct double-walled tubes. They are jointed by radial dissepiments, and more or less constricted, and contain granules and cells, whilst the terminal filaments bear various forms of fructification. In many cases there is a stroma, made up of a number of very small granules, resulting from the subdivision of the granules and cells in the interior of the filaments, and even of the conidia. Some question the vegetable nature of these fungus-elements, and aver that they represent a granular degeneration of normal skin-structure, but no transitional stages have been discovered betwixt the two structures. Further, these fungi can be made to develop the characteristic fructification of the common moulds of undoubted vegetable nature, and similar fungi occur in situations—as the hard structure of corals, &c.—in which they could not have been derived from any kind of epithelial or other animal tissue. Conidia may readily be mistaken for fatty granules and *rice-berd*. But the former reflect light strongly, are nucleated, and unaffected by ether in the least degree.

Effects.—Concerning the effects induced by their growth in the skin, it may be said that fungi act like ordinary irritants, inducing inflammation of the skin, and as the fungi grow equally in all directions from a given centre, the eruption is usually circular. Its signs are most marked at the circumference, where the fungus is in its most active state, but, in addition, the fungus invades the epithelial tissues, grows downwards into the follicles, causing irritation and effusion therein, then gradually attacks the hairs or hair-shafts, absorbing their moisture, separating the component fibres, and causing the hairs to become thickened, more or less opaque, twisted, uneven in size along the shaft, and brittle, so that they easily break. Nothing but the growth of fungi in them can produce the disease of the hair observed in the epiphytic diseases.

VARIETIES.—There are seven clinical varieties of undoubted epiphytic diseases, and an additional one, about which great difference of opinion has been expressed. The seven are as follows:—

1. *Tinea favosa* or *favus*, or honeycomb ringworm, caused by the *achorion Schoenleinii*.

2. *Tinea tonsurans* (ordinary ringworm of the scalp), the fungus occurring in connection with it being termed *trichophyton tonsurans*.

3. *Tinea kerion*, a modification of the last-named, having the same parasite, and being characterised by inflammatory prominence of the follicles, and exudation therefrom of viscid fluid.

4. *Tinea circinata* (ordinary ringworm of the body), including the ringworms of Oriental places.—Burmese, Chinese, Indian ringworms, &c. having the same parasite as *tinea tonsurans*, and only differing from it essentially in the fact of its occurrence on the non-hairy parts.

5. *Tinea sycosis*, or ringworm of the beard; the parasite being *microsporum mentagrophytes*.

6. *Tinea versicolor* or *phytosis versicolor*, the *chlamydia* of English writers; the parasite of which is *microsporum furfur*.

7. *Ongychia parastichia* or *onychomycosis*, parasitic disease of the nails, caused by the growth

in the nail of the fungus of *trinea tonsurans* or *trinea favosa*, in other words, the trichophyton or the achorion.

At one time it was thought that the disease known as *trinea decalvans* was parasitic and caused by the growth of the *microsporum Audouinii*, but this is at present a disputed point. See ALOPECIA.

These several varieties of *trinea* will be described in detail under that heading.

TREATMENT.—The principles of treatment in parasitic disease consist in improving the tone of the nutrition, and in bringing parasitoides into contact with the fungus-elements, so as to ensure their destruction; the latter, however, is a matter of much difficulty when the fungi are imbedded deep in the hair follicle, or in the lower parts of the shafts of the hairs of the scalp. See *TRINEA*. TILBURY FOX.

EPILOITIS (*ἐπιλοιπός*, the omentum).—Inflammation of the epiploon or great omentum. See PERITONÆUM, Diseases of.

EPISPADIAS (*ἐπί*, upon, and *σπᾶς*, I draw).—A malformation of the penis in which the urethra opens on its upper surface. See PREPIS, Diseases of.

EPISPASTICS (*ἐπί*, upon, and *σπᾶς*, I draw).—Substances which, when applied to the skin, are capable of producing a blister. See COUNTER-IRRITANTS.

EPISTAXIS (*ἐπί*, upon, and *σπᾶς*, I drop). SYNON.: Fr *Épistaxis*, Ger *Nasenbluten*.

DEFINITION.—Epistaxis signifies a bleeding from the nose.

ÆTIOLOGY.—Epistaxis is either *traumatic* or *idiopathic*.

The *traumatic* form may be occasioned by violent sneezing, by snuffing up irritating substances, or by direct violence, but in these cases there frequently appear to be general or local predisposing causes, to account for the readiness with which it occurs, such as a hemorrhagic diathesis, an inflammatory or congestive hyperæmia, or some ulceration of the mucous membrane.

The *idiopathic* form of epistaxis frequently occurs in children, particularly boys, just before or about the age of puberty, and in girls as a form of vicarious menstruation. Epistaxis may be one of the forms of bleeding in persons of hæmorrhagic diathesis, in which case it is a source of anxiety and difficulty. Occurring in advanced life, it may be indicative of over-distension or obstruction of the cerebral venous system from chronic Bright's or cardiac disease, and the blood which flows is then often venous in appearance. Occasionally it occurs as a spontaneous relief to determination of blood to the head, in which form the blood generally proceeds from one nostril only. In other instances epistaxis is connected with serious disorder of the blood, as in the specific fevers. Thus it is often associated from the outset with remittent, enteric, typhus, or scarlet fever, and is indeed regarded in some degree as pathognomonic of enteric fever. It may also attend scurvy, purpura hæmorrhagica, splenic disease, pyæmia, and erysipelas, being a sequence of the septic condition.

In its passive form, epistaxis is often associ-

ated with organic disease of the heart, pleurisy, emphysema, or with ascites or ovarian dropsy, on account of pressure on the diaphragm inducing a stasis of the venous circulation. It may occur spontaneously from exposure either to great cold or great heat, or a sudden change from cold to heat, or from the diminution of atmospheric pressure, as in going up high mountains.

SYMPTOMS.—Hæmorrhage from the nose is too familiar to demand description in this place. The flow of blood may be either continuous or drop by drop. As a rule, the escape of blood is from one nostril, bleeding from both being rare. It may last a very short time, or for some hours, and in severe instances for days, causing syncope, or even being attended with fatal results. It is at times met with as occurring periodically.

DIAGNOSIS.—Epistaxis must not be confounded with hæmoptysis, as may happen if the epistaxis takes place posteriorly, and the blood passes into the mouth.

TREATMENT.—When epistaxis is obviously a salutary process, as it incidentally is in a good many instances, it subsides spontaneously where it occurs frequently and acutely, recourse must be had to mechanical, cutaneous and internal remedies. The local application of cold in the form of cold water or ice compresses to the nose, neck, or forehead is most useful, acting as these agents do either directly or by inducing a reflex effect on the vaso-motor nerves. Simple pressure upon the nostril, or upon the septum nasi, by compressing the bleeding nostril with the finger of the opposite hand, while the arm of the affected side is raised above the head, is the most readily practicable and effectual of all measures. The application of mustard over the stomach or upon the ankles is sometimes successful. When simple means fail, astringents, either in the form of solution or powders, may be injected into the cavities, or applied on plugs of lint or cotton-wool, such as alum, acetate of lead, the salts of iron, or gallic or tannic acid.

Internally, the frequent administration of small doses of tincture ferri perchloridi, turpentine, bromide of potassium, or belladonna and quinine may be necessary in cases of periodic attacks.

In very severe cases the operation of plugging the nares, and thereby favouring the formation of a clot, must be resorted to, and the most ready and easiest method is by the employment of Bellocq's sound, or more properly cannula. If, however, this instrument be not at hand, a catheter or an eyed probe should be threaded with a stout silk or hemp ligature, and pushed along the floor of the nose, until it protrudes beyond the velum palati, one end of the thread should now be pulled out of the mouth by the fingers or forceps, and a roll of lint or a piece of sponge tied to it, and then pushed up behind the velum. The catheter and the attached thread being now withdrawn through the nostril, the plug is pulled forcibly against the posterior nares, and by the pressure exerted the hæmorrhage can generally be arrested.

EDWARD BELLAMY.

EPISTHOTHONOS (*ἐπίσθινος*, forwards, and *θῆλον*, I extend).—A synonym for emprosthotonos. See EMPROSTHOTHONOS.

EPITHELIOMA (*ἐπί, upon, ἔλλω, I grow*—epithelium; and *ῥαψ, like*).—A variety of cancer, consisting essentially of epithelial elements. *See* CANCER.

EPITHELIUM, Diseases of.—The different kinds of epithelium must be separately considered, as they differ in their pathological relations, namely, *squamous* and *cylindrical* epithelium of mucous surfaces, *serous* epithelium, or *endothelium*, and finally *spheroidal* or *glandular* epithelium. The last kind will be better treated of under the heads of the several glands.

A. DISEASES OF SQUAMOUS AND CYLINDRICAL EPITHELIUM.—1. **Catarrhal Inflammation.**—

Both varieties of epithelium occurring on mucous surfaces are subject to inflammation, which usually takes what is called the catarrhal form.

Catarrhal inflammation is characterised by hyperæmia, swelling of the tissue, rapid production and casting-off of cells, and increased production of the normal mucous secretion of the parts, without the production of any coagulable exudation, or any layer of new material. The cells thrown off are partly epithelial, partly leucocytes or pus-cells. The secretion contains mucus. The proportion of the various factors of catarrhal inflammation varies greatly, sometimes hyperæmia with swelling, sometimes cell-production, sometimes fluid secretion predominating, and these differences sometimes mark different degrees or stages of the inflammatory process. When the number of leucocytes thrown off is very large, the catarrh becomes purulent, which differs only from the other in degree. Catarrhal inflammation is the ordinary result of irritation applied to a mucous surface, but it persists after the irritation has ceased and has a marked tendency to become chronic. While the chief share in producing and maintaining the phenomena of catarrh must be referred to the condition of the blood-vessels of the mucous membrane, the part played by the epithelial cells in these processes is a point of great interest and importance, though as yet imperfectly determined. These cells, whether squamous or cylindrical, enlarge and alter in shape, while there must be (since so many are shed) a rapid new formation of them, but the seat of this new formation, whether in the normal or the pathological condition, is still obscure. Further, it is not unusual to find swollen epithelial cells which show division of the nuclei or partial division of the cell itself, and others which show within their substance several smaller, roundish bodies, with the general character of young cells. These appearances have been regarded as indicating (1) multiplication of cells by fission, (2) endogenous cell-formation within the mother-cells, and (3) the origin of the numerous pus-corpuscles seen on the inflamed surface. There is, however, no reason for thinking that new epithelial cells are thus formed. By others again the presence of pus-corpuscles or young cells within the epithelial cells is regarded as an unimportant and accidental complication, the young cells which possess the power of migration being absorbed into the protoplasm of the epithelial cells, so as to appear as if originally formed there. The production of vacuoles or

spaces in the altered epithelial elements is also explained in two ways, either as a part of the process of cell-proliferation, or as indicating partial absorption of the substance of the cell. It must therefore be regarded as still uncertain, whether epithelial cells do, by a process of proliferation, give rise to any new elements.

2. **Croupous Inflammation.**—(Croupous inflammation is distinguished by showing, in addition to hyperæmia and swelling, the production of a layer of new material, or false membrane, easily detached from the surface. This form is usually, if not exclusively, seen on surfaces covered with cylindrical epithelium, as in the air-passages. The false membrane composed of fibrin cementing together layers of detached epithelium and leucocytes, does not owe its origin to any alteration of the epithelium itself.

Croupous inflammation of epithelial surfaces has been regarded as always indicating some specific form of inflammation. It now appears, however, that it may be produced by simple irritation, such as that which produces the catarrhal form, provided the irritation be sufficiently intense.

3. **Diphtheritic Inflammation.**—This is a name used with much variation of meaning, but generally to signify a process in which there is production of a false membrane closely adherent to the epithelial surface, and which is accompanied by some degree of necrosis or gangrene. In the production of the diphtheritic false membrane an important part has been assigned to the epithelium, it being held that the new material which appears like exuded fibrin is really produced by a metamorphosis (the so-called *fibrinous transformation*) of the pavement epithelium. It is pretty clear that when this condition occurs on surfaces covered with this variety of epithelium some such change in the epithelium does take place, but not that the membrane is made up wholly or even in any large degree of such altered cells. Moreover, even this cannot be clearly traced on surfaces covered with cylindrical epithelium. The membranes consist in large measure of cast-off epithelium, and also (as the writer holds) partly of fibrin, though the presence of the latter constituent is denied by some authors. It should be noted that the terms croupous and diphtheritic inflammation, as here used, are not synonymous with the diseases named croup and diphtheria.

4. **Fatty Degeneration.**—It is very common to find the protoplasm of both squamous and cylindrical epithelial cells dotted with oil globules, so much so that this must be considered normal, to a certain extent, in some glandular epithelium (as kidney), and does not appear to interfere with the function of the cells. When the fatty change, however, is extensive, and more especially when the whole body of the cell is opaque, the condition must be regarded as one of fatty degeneration (*see* FATTY DEGENERATION). This is seen in the stomach in cases of alcoholism, in poisoning with metals or phosphorus, and in cases which are probably nothing more than chronic catarrh. It is also seen in the alveolar epithelium in pulmonary emphysema. Fatty degeneration appears in epithelium to be a process leading to atrophy.

5 Mucous or Colloid Degeneration.—Epithelial cells, especially in parts which are naturally adapted to the production of mucus, particularly cylindrical epithelium, are liable to undergo a form of degeneration in which a portion of their protoplasm becomes converted into mucous substance, and thus liquefied. Cells having this character are often seen in catarrhal conditions of the mucous membrane of the air-passages, but the change does not appear to occur as a substantive diathesis. It has not been traced in squamous epithelium.

6 Albuminoid (Waxy or Amyloid) Degeneration.—This form comparatively rarely affects epithelial cells, but still in cases of albuminoid disease we may sometimes find that the mucous surface of the intestines is stained with iodine in the characteristic manner. In one or two cases the writer has observed a similar change in the surface of the pelvis of the kidney, and even the bladder, where there has been albuminoid disease of the kidney.

B. DISEASES OF ENDOTHELIUM.—The single layer of flat epithelium found on serous surfaces, which differs so much from the other forms as to be now generally known by another name, *endothelium*, differs also in its pathological relations.

1. **Catarrhal Inflammation** is unknown on serous membranes, their characteristic form of inflammation being exudative and fibrinous, corresponding thus to the

2. **Croupous Inflammation** of mucous surfaces. In this inflammation the endothelium does not necessarily take any part, though when the inflammation is once established the endothelium is, in part, simply shed, in part shows changes of a proliferative kind; cell-division, multiplication, and endogenous cell-formation being observed here with less ambiguity (as it appears to the writer) than in the epithelium of mucous surfaces. Similar changes appear to occur in chronic inflammation of serous surfaces, and to play an important part in the production of fibrous adhesions between opposing surfaces.

3 **Fatty Degeneration.**—Endothelial cells are also subject to fatty degeneration, which may be very clearly seen in surfaces ulcerated by a collection of fluid, as in serous effusions of the peritoneum or pleura.

The other pathological changes of endothelium have not been studied.

The epithelium (or endothelium) lining the inner surfaces of the walls of arteries and veins, closely resembles the endothelium of serous surfaces. It is very subject to fatty degeneration, as may be seen on examining atheromatous arteries. Proliferative changes have also been traced by some observers in the process of occlusion of ligatured arteries or veins obstructed by thrombosis; but they do not appear to play any important part in idiopathic disease.

C. DISEASES OF GLANDULAR EPITHELIUM.—The diseases of glandular epithelium are best spoken of under the head of diseases of the several glands. See BREAST, Diseases of; &c.

J. F. PATRICK.

EPITHEM (*ἐπί*, upon, and *τίθημι*, I place).

A general term for a class of external applications which are soft and moist, such as poultices and fomentations. See FOMENTATIONS, and POUltICES.

EPIZOA (*ἐπί* upon, and *ζῷον*, an animal).—A term formerly much used by zoologists to characterize a peculiar and distinct group of parasitic creatures which attach themselves to fishes, but now more generally employed to embrace all kinds of parasites having the habit of residing in or upon the surface of the body of man and animals. In the writer's judgment the more comprehensive term *Entozoa* is preferable, and the distinctions which have been created as to the relative value of these two terms ought to be abolished. In any case it should be understood that the equivalent terms *epizoa* and *entozoa* have no zoological significance, being simply employed for convenience' sake when we are speaking of external parasites, of whatever character, in contradistinction to the term *entozoa*. The *epizoa* comprise such parasites as lice and mites (*Dermatozoa*), and the term might also be made to include fleas, bugs, and other creatures whose residence on the surface is only occasional, and of very short duration. See PARASITES, and ENTOMOZOA, also ACARINA, DEMODEX, CHINCH, PEDICULI, and (ENTOMIA) T. N. CONNOLD.

EPULIS (*ἐπί*, upon, and *ὄδον*, the gum). See MOUTH, Diseases of.

EQUINIA (*ἑquina*, a horse).—A synonym for glanders. See GLANDERS.

EQUINIA MITIS See GLANDERS.

ERETHISM (*ἐρεθίζω*, I irritate).—A condition of excitement or irritation, affecting either the whole system or a particular organ or tissue. The word has been especially applied to the condition of the body in the early stage of acute diseases and also to that induced by the too free use of mercury (*mercurial erethism*). See MERCURY, Poisoning by.

ERGOTISM.—SYNONYM: *Morbus cerealis*, Fz. *Ergotisme*, Ger. *Ergotismus*, *Kriebelkrankheit*.

DEFINITION.—A disease due to the action of ergot upon the organism.

ETIOLOGY.—This disease derives its name from the fact that it is the result of the ingestion of ergot—the stroma of a fungus called *Claviceps purpurea*, which grows parasitically in the ear of the lye. In some seasons this form of blight affects the grain so extensively that ten per cent. of the meal may consist of ergot. The phenomena to be described as symptoms of ergotism have been regularly and exclusively traced to the use of articles of food made from rye-meal thus contaminated. The appearance and severity of the disease vary with the amount of ergot consumed. Children at the breast are never attacked. Ergotism has frequently broken out in well-marked epidemics, after unfavourable harvests. In ruder times it constituted a severe form of scourge; but now it usually occurs sporadically, or is limited to families or small communities.

ANATOMICAL CHARACTERS.—Nothing definite is known respecting the morbid anatomy of ergotism.

STIMULUS.—Within a few days of the first ingestion of meal poisoned with ergot, the ordinary phenomena of irritant poisoning are developed, namely, vomiting, diarrhoea, severe abdominal pains and cramps, and general depression—giddiness and headache being specially marked.

Along with the preceding, certain special symptoms gradually make their appearance. The first and most characteristic of these is formication, attended with severe itching of the skin of the extremities. The other special senses, such as vision and hearing, may also become disordered. Occasional spasms occur in the muscles. Ravenous hunger is said to be a striking symptom in some instances. The pulse is infrequent and small. Respiration is not markedly disturbed.

The remaining phenomena peculiar to ergotism are usually described as belonging to two forms, the *gangrenous* and the *spasmodic*, according as the circulation or the nervous system is chiefly affected.

a. Gangrenous Ergotism.—Gangrene, due to ergot, is peculiar only in respect of its cause. The toes, fingers, feet, ears and nose are the parts most commonly attacked. The incipient discolouration, pain, and swelling are observed within a period of two days to three weeks from the commencement of the other toxic symptoms. The necrotic process passes through the ordinary stages of development, may be either 'wet' or 'dry,' and advances to complete separation of the part, if this have not been previously removed by operation.

b. Spasmodic Ergotism.—The leading symptom of this form of the disease is the occurrence of severe intermittent cramps or painful spasms, specially affecting the lower extremities. These develop into tonic contraction of the muscles, with fixation of the limbs; and end perhaps in general convulsions, prostration, unconsciousness, and death. Abortion does not appear to be of frequent occurrence.

COURSE, DURATION, AND TERMINATIONS.—Many cases of ergotism are acute rather than chronic, but when gangrene appears, the course may be very protracted and variable. Spasmodic ergotism may last from two weeks to as many months. The mortality is said to have fallen from sixty to ten per cent. In a few cases, resolution occurs in affected extremities.

PATHOLOGY.—Beyond its effect as an irritant poison, the specific influence of ergot is exerted upon the organs of circulation, upon the central nervous system, and upon the uterus.

The Circulation.—Ergot produces a remarkable slowing of the cardiac rhythm, the arteries become contracted, with diminution or even disappearance of their channel, or formation of thrombi; the blood-pressure falls, and the veins become dilated and distended. The most recent and consistent theory respecting these phenomena is, not that the muscular coats of the arteries actively contract, but that the venous walls are primarily relaxed. The veins are thus overfilled, and the arteries drained of blood; the blood-pressure is lowered; and the heart being insufficiently fed, contracts feebly and slowly.

The Nervous System.—Certain of the spinal

centres, both motor and sensory are first stimulated and afterwards paralysed by ergot—directly, according to some authorities, indirectly according to others.

The Uterus.—The unquestionable action of ergot upon the uterus is explained by some authorities as due to stimulation of the centre for the uterus in the cord. Others consider that ergot acts upon the muscular fibres of the organ either directly or indirectly through the blood-supply.

Whatever may be the value of the several 'explanations' of the action of ergot, the facts connected with it suffice to account for the specific phenomena of ergotism. The small, feeble, and infrequent pulse are due to interference with the circulation, while the painful spasms, as well as the formication and other sensory disturbances, are the direct result of the action of the poison upon the cord. The gangrene may also be partly due to the latter cause.

DIAGNOSIS.—The occurrence of gangrene in a number of young and previously healthy persons should remove all difficulty from the diagnosis of ergotism. The spasmodic form of the disease may be distinguished from epidemic cerebro-spinal fever by the absence of pyrexia.

PROGNOSIS.—The prognosis depends chiefly upon the early recognition and removal of the cause. The probability of the escape of affected extremities may be estimated by the degree to which the gangrenous process had advanced.

TREATMENT.—The treatment of ergotism consists in removing the cause of the disease; in hastening the elimination of the poison by the cautious administration of emetics and purgatives, in allaying the symptoms of gastro-enteritis, and in supporting the strength of the patient by internal and external stimulants, such as alcohol, warmth, and friction. Gangrene must be averted by careful local stimulation, by means, for example, of warm fomentations; or treated, if it should arise. See GANGRENE.

J. MITCHELL BRUCE.

EROSION (*erodo* I gnaw)—A superficial destruction of tissue, caused especially by friction, pressure, corrosion, or certain forms of ulceration.

EROTOMANIA (*eros* love, and *mania*, madness)—**SYNON.**—Love-melancholy, *Nutyrinis* (in men), *Nymphomania* (in women), *Fr. Monomanie érotique*, Ger. *Liebeswuth*.—Insanity characterized by excessive sexual excitement, sometimes symptomatic of cerebral lesion, sometimes of disorder in the reproductive organs. See INSANITY.

ERRATIC (*erro*, I wander)—Wandering shifting, or irregular. Applied to pimples, eruptions on the skin, and other morbid phenomena when they shift or move from place to place.

ERUCTION (*eructo*, I belch).—**DEFINITION.**—The sudden escape or expulsion of gas from the stomach upwards, with or without an admixture of portions of liquid or solid food, or of gastric juice, or other liquids.

DESCRIPTION.—The act of eruction may be voluntary or involuntary. In the former case a small portion of air is first swallowed, and by

the over distention thus produced the escape of a portion of the gaseous contents of the stomach is favoured. When involuntary, we must suppose that the cardiac orifice, which is closed in the normal state of digestion, is relaxed, and thus permits the rejection of portions of undigested matter. From the violence with which eructations often take place, we may also assume that the muscular coat of the stomach contracts spasmodically at the same moment that the relaxation of the cardiac opening occurs. The nature of the material rejected varies greatly. Sometimes it is tasteless, in others acid, and in rarer instances alkaline.

ETIOLOGY.—Eructations occur in all gastric diseases attended with an undue formation of gas. They are constantly complained of in atonic dyspepsia, more especially in that form which occurs in elderly people, and are probably the result of an imperfect contract on of the stomach, preventing the due expulsion of the digested food into the intestine. They form a prominent and distressing symptom in dilatation of the stomach. In such cases the patient often complains of a sense of fermentation in his abdomen, and immense quantities of gas are expelled, generally mixed with an acid or acid fluid.

TREATMENT.—The indications in the treatment of eructations are to prevent the decomposition of food, and the formation of gases and other products; to restore tone to the stomach, and remove any morbid condition of this organ, and to give remedies with the view of absorbing gases, or assisting the act of eructation. See STOMACH, Diseases of. SAMUEL FENWICK.

ERUPTION (*eruptio*, a bursting forth)—This term is commonly applied to a pathological manifestation in the skin, more or less general, sometimes marked by colour, sometimes by prominence, but more frequently by both. When sudden and hyperemic, a term derived from the effluence of a plant, namely, *exanthema*, is employed, as in the instance of the exanthematous eruptions—scarlatina, rubella, roseola, and variola. The term is equally applicable to less acute forms of dermatosis, such as urticaria, eczema, impetigo, ecthyma, acne, and favus, and is also used for still more chronic forms of disease, for example, lepra vulgaris, and for outgrowths of the skin, due to alteration of nutrition, as in the instance of warts and molluscous tumours.

ERASMUS WILSON.

ERYSIPELAS (*érysipé*, I draw, and *élas*, near)—SYNON.: Lat *Erysipelus*. Fr *Erysipèle*, Ger *Erysiphus*. Popular names—St Anthony's Fire (English), the Rose (Scotch), *der Rothlauf*, and *die Rose* (Ger).

DEFINITION.—Inflammation of the integument tending to spread indefinitely (*Royal College of Physicians' Nomenclature of Diseases*). The vagueness of this definition indicates the looseness with which the term is employed. The features common to all inflammations usually spoken of as erysipelatous are fever, usually preceding the local phenomena; and an inflammation tending to spread indefinitely by means of the lymphatics and lymphatic vessels of the affected part.

SUMMARY OF VARIETIES.—Erysipelas is usually divided into (a) Simple Cutaneous, (b) Phlegmonous or Cellulo-cutaneous, and (c) Cellular, or Diffuse Cellulitis (Nunneley). In addition to these three chief varieties, erysipelatous inflammation of the lymphatic vessels and veins, and of serous and mucous membranes, is also described.

PATHOLOGY.—All the inflammatory affections thus loosely classed together, as erysipelas in its various forms, have one feature in common. They all belong to the class of infective inflammations—that is to say, the inflammatory products possess the property of setting up an inflammation similar in character to that at the original focus in any part with which they may come in contact. In erysipelas these infective products diffuse themselves by the lymphatic vessels and lymph-spaces, and thus set up a spreading lymphatic inflammation. As the poison diffuses itself, it seems in most cases to lose its intensity, and thus the spreading is finally arrested. Of the exact nature of the poison we know nothing definite. As in other infective inflammation the exudation-matter contains minute organisms (*micrococci*), but the part these play in producing the disease, and their mode of origin, are matters of dispute. The poison, whatever it may be, is communicable from one individual to another. It is probable however, that simple cutaneous erysipelas differs entirely in nature from cellulo-cutaneous and cellular erysipelas. The two latter are in most cases purely local in origin, and the poison which causes them probably varies, both physically and chemically, in different cases. In some cases it may be merely decomposing animal-matter, in others it may be something as truly specific as the infective products of malignant pustule or the poison of a venomous reptile. The effect produced by the inoculation of such poisons depends to a great extent upon the susceptibility of the individual. This is increased by all bad hygienic conditions and above all by the abuse of alcohol and consequent visceral disease. When these affections commence apparently spontaneously, careful inquiry will almost invariably show that the starting point has been some local injury occurring in a person previously in ill-health. Simple cutaneous erysipelas, on the other hand, partakes much more of the nature of an acute specific fever. It is communicable not only by direct inoculation, but by infection; there is a distinct period of incubation, the duration of which is uncertain (variously stated from a few days to two weeks), the constitutional symptoms precede the local inflammation, often by a day or more, and the disease occurs in epidemics. It differs from other acute specifics in its extremely irregular course, and by its not conferring on the patient any immunity from a second attack; in fact, one attack predisposes to another. Two views are therefore held by different authors with regard to it. On the one hand some consider it primarily a general disorder, the local manifestation of which is a diffuse inflammation starting from any wound that may exist on the person of the patient, or, failing that, choosing by preference the points of junction of mucous membrane and skin. On the other hand it is

described as originally a purely local inflammation, infective in character, and secondarily giving rise to constitutional disturbances. Others again suppose both forms to exist, and describe them as *transient* or *ergoid*, and *idiopathic* or *medical* erysipelas. At the present time the question cannot be considered as definitely settled.

ETIOLOGY—I. *Infection*. Erysipelas is undoubtedly infectious and inoculable, as the experience of hospitals sufficiently teaches us. Its power of infection is, however, not very great, certainly much less than that of measles or scarlet fever, and probably about equal to that of diphtheria. The development of the disease will depend, therefore, to a great extent upon the patient and his surroundings.

II. *Predisposing causes*. A. *In the patient*.

1. *Constitutional predisposition*. This is said to be increased by a previous attack and sometimes to be hereditary. 2. *Disease of some important viscus, especially liver and kidneys*. 3. *The presence of a wound*. 4. *Age*. This has little effect; the disease affects all ages alike. 5. *Sex*. Erysipelas is said to be most common in women, especially at the menstrual period. 6. *Intemperance and want of proper food* are great predisposing causes.

B. *In the patient's surroundings*. 1. *Meteorological conditions*. East winds, low temperature, excessive moisture, cold and heat, have all been considered causes. It is said to be most common in spring and autumn. On all these points there is no really reliable evidence.

2. *General hygienic conditions*. Overcrowding in hospitals, want of ventilation, dirt of all kinds, bad food and impure water are all predisposing causes.

3. *Epidemic influences*. Erysipelas undoubtedly occurs in epidemics, and the type of the disease often varies in different outbreaks.

We shall now proceed to discuss in detail the several varieties of erysipelas summarised above.

1. *Simple Cutaneous Erysipelas*.—This is the most typical form of the disease.

ANATOMICAL CHARACTERS.—The post-mortem appearances of erysipelas are by no means characteristic. The redness of the inflamed area of course fades after death, leaving a faint yellowish tint. The skin feels hard and inelastic, and the subcutaneous tissue contains an excess of serous fluid. In very acute cases there may be the usual signs of blood-change seen in all malignant fevers—early post-mortem staining, imperfect coagulation of the blood, subserous petechiæ, swollen and soft spleen, and cloudy swelling of the liver and kidneys. Hüller states that microscopic examination of the blood before death shows many of the white corpuscles to have undergone degenerative changes and become converted into masses of highly refracting granules. Busk has described plugs of such altered corpuscles in the small vessels of the lung, and Bastian has observed a similar condition in the vessels of the brain. Microscopic examination of the affected part of the skin shows large numbers of migrating leucocytes, lying in the spaces of the fibrous tissue, amongst the fat-cells, and in the lumen of the lymphatic vessels. They are especially abundant

round the small vessels. Lukomsky (*Vierteljahr Archiv*, Band lxx.) has described the presence of micrococci filling the lymph spaces and lymphatic vessels at the advancing margin of the erysipelatous inflammation. These are not observed where the rash is receding, nor in those parts which have been affected for any length of time. This observation has been confirmed by subsequent observers.

SYMPTOMS.—In simple erysipelas the constitutional symptoms usually precede the local. The invasion is marked by chilliness, seldom by an actual rigor, loss of appetite; general malaise, nausea, but seldom actual vomiting; headache; pain in the limbs, and the usual signs of pyrexia. The invasion is tolerably sudden. The temperature rapidly rises to about 103° F. or higher. The rarer symptoms at this stage are epistaxis in adults, and convulsions in children. Usually within twenty-four hours of the invasion the characteristic cutaneous inflammation appears. It may, however, commence simultaneously with the febrile disturbance, or be delayed even for two or three days. Frequently the lymphatic glands nearest to the part are swollen before the cutaneous eruption appears, afterwards they are invariably enlarged and tender. The local inflammation usually, if not always, starts from some wound, scratch, or abrasion. It commences indifferently in a fresh wound or a granulating sore. When no wound can be recognised as its starting point it usually starts from the junction of mucous membrane and skin, most commonly from the corner of the eye, causing a swelling across the bridge of the nose. It may also start from the angle of the mouth, the external auditory meatus, or the anus. It may commence in the nasal fossæ or pharynx, and extend outwards to the skin of the face. Possibly in all cases it starts from some slight abrasion which is scarcely to be detected (*Truensen*). The inflamed skin is bright red in colour, with sometimes a yellowish tinge, the redness advances in all directions, but usually most rapidly in that of the lymph-stream. The advancing margin is irregular, sharply defined, and very slightly raised. The cutis is oedematous, and pressure with the finger-nail leaves a deep and abiding mark. Where the subcutaneous areolar tissue is lax, as in the eyelids or scrotum, it also becomes greatly swollen. In the limbs the subcutaneous swelling is great only in severe cases. In many cases small vesicles rise, which may coalesce, forming blebs of considerable size. These ordinarily contain clear yellow serum which, in bad cases, may be stained with blood-pigment. As these bullæ burst they dry up forming scabs on the surface, but no ulceration takes place beneath these scabs. The inflammation has but little tendency to end in suppuration, when this does occur it is in those parts in which the oedema has been greatest, as the eyelids. There is heat, tension, and pain in the affected part, and a peculiar sensation of stiffness, which may even precede the appearance of the redness. The febrile symptoms which usher in the attack remain unrelieved so long as the redness continues to spread. The pulse is at first quick and full, but it soon loses force, and in bad cases becomes extremely rapid and feeble. It is by the

pulse, more than anything else, that the gravity of the case is marked. The temperature seldom rises above 106° F., though 107.5° F. has been recorded. The daily variations are not great, there being merely the usual slight morning fall and evening rise. Delirium is not uncommon at night, even in mild cases. In erysipelas of the head it may be a prominent symptom. It is usually due to the blood-condition, and not, as was formerly supposed, to extension of the inflammation to the membranes of the brain. This, however, does occur in rare cases, especially in erysipelas of the orbit or in that following a compound fracture of the skull. The tongue is always foul and usually dry, in bad cases becoming cracked and brown, with sordes on the lips and teeth. In erysipelas of the head the fauces are always red and congested, even when the inflammation has not actually extended to that part. The bowels are sometimes confined, but disturbed with offensive motions is liable to occur. There is nothing characteristic about the urine. As in other acute febrile diseases it frequently contains a small quantity of albumen. In erysipelas of the head when the disease reaches its height, the appearance is often hideous in the extreme the features being completely obliterated by the swelling of the lax subcutaneous tissue, and the face further disfigured by the scales formed by the dried blebs. The duration of simple erysipelas is very uncertain. The cessation of the disease is marked by the inflammation ceasing to extend, and by a simultaneous fall of temperature, often very sudden. This may occur as early as the fifth day, or be delayed till the end of the second or middle of the third week. As the rash fades its margin loses its distinct outline, and the redness shades off insensibly. It is not uncommon to see the inflammation spreading at one part, fading at another. After the subsidence of the inflammation there is desquamation of the cuticle, and in erysipelas of the head often complete loss of hair, which is, however, never permanent. Suppuration occasionally takes place in the nearest lymphatic glands. Even after a mild attack the patient's strength is much reduced, and he often remains weak and anæmic for a considerable time. Relapses are by no means uncommon. When death occurs from simple cutaneous erysipelas, it arises most frequently from exhaustion. It may also be due to the gravity of the blood-charge. Occasionally the fatal termination is preceded by violent delirium ending in coma. Sometimes it is due to some complication, as pleurisy or pneumonia, or in very rare cases meningitis. When sloughing of the skin or suppuration occurs, death may take place from septicæmia or pyæmia.

VARIETIES.—Some writers have divided simple erysipelas into *medical* and *surgical*—or *idiopathic* and *traumatic*—and have described these varieties as distinct diseases. They are, however, probably identical, for the following reasons:—they closely resemble each other in mode of invasion, course, and pathological changes; infection from so-called idiopathic erysipelas will give rise to the traumatic form in patients suffering from an open wound; and during an outbreak of erysipelas in a surgical ward patients without open wounds are occasionally attacked by the

idiopathic form. Erysipelas has also been subdivided according to the part it attacks, as erysipelas faciei, capitis, acroti, &c.

Erysipelas occasionally affects the mucous membrane of the pharynx and upper part of the larynx. This form presents some peculiarities, and is spoken of as *erysipelatous pharyngitis* and *laryngitis*. The invasion and constitutional symptoms are similar to those of simple cutaneous erysipelas. There is a bright redness of the back of the pharynx and the fauces, always accompanied by considerable œdema of the soft palate and some swelling of the tonsil. The glands at the angle of the jaw are swollen and tender. The danger of this affection arises from extension to the glottis, causing œdema glottidis, with intense dyspnoea, expiration being more easy than inspiration, and both liable to obstruction by spasm. In such cases tracheotomy or laryngotomy may be required at any moment, to prevent death from asphyxia. In other cases the inflammation may extend forwards and appear on the face, either at the nostril or mouth, and afterwards extend as ordinary facial erysipelas.

Erysipelas occasionally attacks new-born infants, starting from the navel or genitals. This form has been spoken of as *E. neonatorum*. Serous membranes, especially the peritoneum, are said sometimes to be affected by erysipelas following wounds. In lying-in women the poison of erysipelas seems, in common with that of many other unhealthy inflammations, to be capable of causing puerperal fever.

Dermatologists have, according to their wont, invented a name for every possible variation. Thus when the inflammation spreads at one part while fading at another it has been called *E. ambulans* or *eritemum*, when spreading in a winding course, *E. serpens*, when causing small vesicles, *E. vesiculare* or *milare*, when blebs form, *E. bullosum*, when there is much swelling, *E. œdematosum*, &c. Such names are useless, and may be multiplied *ad infinitum*.

DIAGNOSIS.—When the eruption is fully developed it is scarcely possible to mistake the disease. During the stage of invasion, before the appearance of the rash, diagnosis is impossible. Simple diffuse inflammation round a wound or abscess is distinguished from erysipelas by the absence of the characteristic invasion, and by the sharply defined border. Simple erythema differs from erysipelas in the absence of fever, and in the eruption being composed of numerous isolated patches. Occasionally, in malignant small-pox, there may be much redness and swelling of the face before the appearance of the vesicles, but the symptoms of invasion are much more severe than those of erysipelas.

PROGNOSIS.—The prognosis depends chiefly upon the gravity of the general symptoms. The following are bad signs:—high fever, violent delirium, excessive diarrhoea, early prostration, and very dry tongue with sordes. The extent of the inflammation is of less importance. Old age, disease of the kidneys or liver, and especially chronic alcoholism, add greatly to the gravity of the case. When erysipelas affects the pharynx there is always danger from œdema glottidis. In uncomplicated cases the death-rate is not high.

Of 35 cases treated in the medical wards of University College Hospital from 1872 to 1876, only one died, and he was suffering from chronic Bright's disease.

TREATMENT.—1. *Constitutional.* Erysipelas being a most exhausting and depressing disease, no antiphlogistic treatment is ever justifiable. Clear the bowels at the commencement of the attack, but avoid violent purgation. Only two drugs have any reputation in the treatment of erysipelas. The tincture of perchloride of iron in large and repeated doses, has been strongly recommended by Dr. Reynolds and others, and is stated by some to act as a specific. To be of any use it must be given in doses of forty minims every four hours. Acetate if administered as soon as the temperature begins to rise is said to cut the attack short. It may be given in half-minim or minim doses of the tincture at first every quarter of an hour for one or two hours, and afterwards hourly till the skin becomes moist and the temperature falls, but its effects must be very carefully watched, to avoid dangerous depression. The diet must be as nourishing as possible, beef tea, eggs and milk, &c. Solid food can never be taken during the advance of the disease. Stimulants are usually required, and the amount must be regulated by the pulse. Large quantities are often necessary.

2. *Local.*—Local treatment is very various. Warmth and avoidance of variations of temperature are essential. Cold is utterly inadmissible, it aggravates the inflammation, and tends to cause suppuration or even sloughing. Hot fomentations or hot baths may be employed when the part affected renders them admissible. In other cases dry warmth must be used, it is best obtained by covering the affected part with a thick layer of cotton wool. Poultices should be avoided, as they needlessly irritate the skin, and are dirty and apt to get cold. With the application of warmth innumerable varieties of local applications have been recommended. These may be divided thus.—(a) *Indifferent applications.* These are intended only to exclude the air, but they have the disadvantage of shutting in the secretion of the skin. The most common of these are collodion, oil, and a thick layer of flour or starch under cotton wool. (b) *Sedative applications.* The most important remedy of this class is belladonna. It is best applied as a paint composed of equal parts of the extract and glycerine. It is especially useful when there is much inflammation of the lymphatic vessels and glands. (c) *Powerful Astringents.* Valette of Lyons recommends a 30 per cent. solution of perchloride of iron; Higginbottom a solution of the 'brittle stick of nitrate of silver' 20 grains to one drachm of water. Before applying either of these the skin must be carefully washed with soap and water to free it from grease. The perchloride of iron must be rubbed in with a glove. (d) *Antiseptic applications.* Marshall recommends cressets made into a paste with tallow; Dewar, equal parts of sulphurous acid (S.P.) and glycerine, tincture of iodine is a common application. Lately Huxer has practised the subcutaneous injection of a 30 per cent. solution of carbolic acid. He states that this causes an immediate arrest of the inflammation for a small distance round the

puncture; if, therefore, the treatment is adopted at so early a stage that the area of inflammation can be surrounded by four or five punctures the disease may be checked. Beyond this there would be danger of carbolic acid poisoning. (e) *Dressing & limiting line* in front of the advancing rash. This has been done with solid nitrate of silver, and with blistering fluid. It is utterly useless.

Erysipelas of the fauces is best treated by the local application of a strong solution of perchloride of iron. If there is œdema glottidis the swollen parts must be scarified, and if that fails to give relief, tracheotomy may be necessary.

II *Phlegmonous or Cellulo-cutaneous Erysipelas* was described by Dupuytren under the name of 'diffuse phlegmon'.

ANATOMICAL CHARACTERS.—Incisions made into the inflamed part in the early stages show the spaces of the areolar tissue distended with serous fluid, a little later on the fluid is found to be curdled, resembling thin pus, later still the subcutaneous cellular tissue is represented by masses of shredily sloughs soaked in a puriform fluid. Unless exposed to the air by incisions or by sloughing of the skin these sloughs are free from any odour of decomposition and contain no gas. There is nothing characteristic in the post-mortem appearances of the internal organs.

SYMPTOMS.—The invasion is usually marked by chilliness or a rigor, elevation of temperature, nausea, headache, and general malaise. The local inflammation may commence in some wound or abrasion, but it may also arise spontaneously. From the beginning there is marked œdema of the subcutaneous tissue. The skin is reddened, but the margin of the redness is not sharply defined, and swelling and tenderness of the lymphatic glands is often absent. As the area of inflammation extends, the affected part becomes tense and brawny, and vesicles or large blebs form. The tension may become so great that firm pressure with the finger scarcely makes any impression. In a few days from the commencement of the disease, the greater part of a limb may be involved. If unrelieved by treatment the tint of the redness becomes more dusky, and dark purple patches appear. At the same time the tension becomes less, and gives place to a soft, boggy feeling, indicating sloughing of the subcutaneous cellular tissue. Then livid patches appear, which break down into sloughs. As these sloughs separate, large shredily masses of gangrenous cellular tissue can be drawn out, leaving the undermined skin connected with the deeper parts only by bands containing the larger vessels. Finally, the remaining skin being insufficiently nourished may thin and melt away leaving large tracts of the fascia and muscles beneath exposed to view. In this way if proper treatment be not adopted in time, the greater part of a limb may be denuded of its cutaneous and subcutaneous covering. The extreme stage may be reached in a week or ten days, but a longer time usually elapses before all the sloughs are separated. In the earlier stages there is much burning and tense pain, but this subsides as gangrene sets in. The constitutional symptoms are grave from the beginning. There is high fever, the thermometer often

reaching 105° F. The tongue is dry and brown, and sordes accumulate on the lips and teeth, there is total loss of appetite; and diarrhoea is a frequent symptom. The pulse, at first full and bounding, soon loses force, becoming rapid and weak. Delirium, usually of the martering type, is always present in severe cases. Death occurs from exhaustion or from some complication, such as pneumonia, pleurisy, &c. During the separation of the sloughs septicaemia and pyæmia are of frequent occurrence. The disease most commonly attacks one of the limbs, but it is occasionally seen in the scrotum, and a peculiarly virulent form has been described as affecting the face. Phlegmonous erysipelas most commonly occurs in adult patients of broken constitution, suffering usually from the effects of the abuse of alcohol, or from some disease of the liver or kidney.

DIAGNOSIS.—From simple erysipelas the phlegmonous form is distinguished by the great swelling and brawny hardness, by the want of a sharply defined edge, and by the early tendency to sloughing, from spreading gangrene by its slower progress, and the absence of the rapid decomposition and development of gas in the tissues. Acute necrosis somewhat resembles it, but this disease is limited to young subjects, the swelling is less brawny, and when pus forms there is distinct fluctuation and not the boggy feeling of phlegmonous erysipelas.

PROGNOSIS.—The prognosis is always grave, especially if there is any delay in adopting the proper treatment. Early failure of the heart's force, excessively dry tongue, diarrhoea and vomiting are bad signs. The gravity of the case increases directly with the area affected.

TREATMENT.—The patient must be supported by good beef-tea, milk and eggs, and stimulants are usually required to be freely given. No depletory measures are ever justifiable. Ammonia and bark is sometimes of service. *Locally* the treatment in a very mild and doubtful case must consist in the application of hot fomentations, and extract of belladonna made into a paint with an equal amount of glycerine. As soon as there are any signs of tension, free incisions must be made to relieve it. The patient's danger will be greatly lessened if these are made with all the precautions of Lister's antiseptic method.

III. Diffuse Cellulitis, or Cellular Erysipelas.—In this disease the inflammation is confined to the subcutaneous cellular tissue, or to the planes of areolar tissue amongst muscles or beneath fascia. The course of the inflammation is similar in many respects to that of phlegmonous erysipelas, the only important difference being that the skin remains unaffected, or is only implicated in the later stages as a consequence of the sloughing of the subcutaneous tissues.

ANATOMICAL CHARACTERS.—The post-mortem appearances are similar to those of phlegmonous erysipelas.

SYMPTOMS.—The local signs of diffuse cellulitis when occurring in the subcutaneous tissue or beneath the superficial fascia, are marked œdematous swelling, gradually becoming brawny, slight redness of the skin, and usually mottling from over-distension of the superficial veins.

There is no sharp limit to the swelling. There is intense tensile or burning pain, increased by movement, and acute tenderness on pressure. The neighbouring lymphatic glands are in most cases swollen and tender. As the disease advances, the swelling becomes doughy, and possibly an indistinct sensation of fluctuation may be felt. The skin now becomes redder, and the gangrenous inflammation may even extend to it, unless prevented by treatment. An incision in the œdematous or brawny stage merely shaves the areolar spaces distended with serum, sometimes clear, more often turbid. If the incision be delayed till the later stages the affected cellular tissue is reduced to a mass of shreds sloughy soaked in pus. Gas does not form amongst these sloughs till after air has been admitted from without. In mild cases the inflammation may localise itself, and lead to the formation of a large abscess. The constitutional symptoms are always grave. The temperature is high, 104° to 106° F. There are the usual symptoms of fever, the tongue is foul and speedily becomes dry, vomiting and diarrhoea are not uncommon, the pulse, at first quick and full, soon becomes feeble and rapid. There is almost always delirium. The disease usually runs a rapid course, two or three days sometimes being sufficient for it to reach its extreme stage.

Diffuse cellulitis, as above described, is most frequently the result of a poisoned wound, it may then start from the wound or make its appearance at a distant part. It forms the most fatal variety of post-mortem wound; and, as is well known, in such cases the puncture may appear healthy, whilst the areolar tissue in the pectoral region may be the seat of most acute diffuse inflammation. The bite of the less poisonous reptiles causes a similar diffuse inflammation. Diffuse cellulitis of the pelvis is a common cause of death after lithotomy, and is not uncommon in women after labour. Diffuse cellulitis beneath the perineal aponeurosis is of frequent occurrence after sculp wounds. Occasionally the disease arises spontaneously, and it is then most common in the upper limb, but it has been seen in the areolar tissue of the neck and in many other regions. In pyæmia and septicaemia patches of diffuse cellulitis may appear in intermuscular spaces, or in the subcutaneous tissue.

DIAGNOSIS.—The diagnosis of cellulitis is often difficult when the mischief is deep-seated. The œdema, pain, and tenderness, with the severe constitutional symptoms, are the chief guides; but even when these are well marked, the extent of the inflammation, and the necessity for active treatment are often difficult to determine.

PROGNOSIS.—This depends much upon the cause and upon the previous health of the patient. It is a very bad sign when the gravity of the general symptoms is out of proportion to the local mischief. In the pelvis cellulitis may be fatal from peritonitis; in the neck it is very fatal, it is much less dangerous in the limb. When it occurs as a part of pyæmia or septicaemia the prognosis is of course very grave.

TREATMENT.—Early incisions into the inflamed cellular tissue, with antiseptic applications, and abundant support, form the only reliable treat-

ment in severe cases. In slight cases the application of extract of belladonna and glycerine (equal parts), with hot fomentations, may lead to resolution or limitation of the inflammation.

IV. Erysipelatous Lymphangitis.—Inflammation of the superficial lymphatic vessels is a common accompaniment of all varieties of erysipelas; but in some cases it forms by far the most prominent local morbid condition.

SYMPTOMS.—This affection is characterised by red lines running in the course of the lymphatic vessels from some local sore or wound. The lines are at first tolerably sharply defined, and about a quarter of an inch in width, but after a short time they spread out and several may coalesce, forming a patch exactly resembling simple cutaneous erysipelas. There is slight oedema, some pain and stiffness, and acute tenderness on pressure. The lymphatic glands to which the vessels lead are swollen and tender. The constitutional symptoms are the same as in simple erysipelas.

DIAGNOSIS.—This affection can only be mistaken for phlebitis, but the diagnosis is easily made by observing the course of the lines, and by the absence of the knotted cord formed by the coagulation of the blood in an inflamed vein.

TREATMENT.—The treatment is the same as in simple erysipelas. The extract of belladonna and glycerine is especially useful in this form of erysipelatous inflammation.

V. Erysipelatous Phlebitis.—Inflammation of the superficial veins, rapidly spreading in the course of the circulation, accompanied by thrombosis, redness of the skin, and acute tenderness has been supposed by some authors to be erysipelatous in character. The only evidence in favour of this view is that the invasion and the constitutional symptoms resemble those of erysipelas, and that the affection is not uncommon during epidemics of erysipelas. See **VENA DISEASES** of.

Various other diseases have been classed as erysipelatous: the chief of these are whitlow, some forms of puerperal fever, and diffuse peritonitis after operations affecting the peritoneum; all these will be described elsewhere. Diffuse inflammation not unfrequently occurs after punctures made to allow of the escape of the fluid in the dropsy of Bright's disease. That punctures made into feebly nourished tissues lathed in decomposable serous fluid should set up diffuse inflammation is not surprising, but evidence is wanting to prove that such inflammation is necessarily connected with erysipelas.

MARCUS BRCK.

has disappeared the skin is either normal, or remains slightly pigmented or desquamated. Generally there is an increase of temperature, with slight feverish symptoms. Erythema may be either *symptomatic* or *idiopathic*.

a. Symptomatic Erythema.—**ETIOLOGY AND VARIETIES.**—Erythema occurs in rare instances after the administration of drugs. Cases are recorded after the ingestion of arsenic, belladonna, chloral, copaiba, cubeba, digitalis, iodides, opium, quinine, salicylic acid, stramonium, strychnia and turpentine. The rash usually appears immediately after the absorption of the medicine into the circulation, after arsenic it appears at a later period.

Exposure to heat or cold, and contact with various acid or poisonous substances are also common causes of erythema. Friction and, in the absence of cleanliness, the secretions of the skin itself may give rise to it, as when *erythema intertrigo* is produced between the scrotum and thighs by the irritation of profuse sweat and sebaceous secretions. The blush of shame and anger is an erythema produced by the immediate action of the vaso-motor nervous system.

Varicella, cholera, enteric fever, rheumatic fever, and various other less distinctly defined febrile conditions, are frequently accompanied during various stages of their course by a more or less generally diffused and mostly ephemeral form of erythema.

The *roseola infantilis* of authors is an erythema that accompanies intestinal disturbance, teething, and various other disordered conditions of the system in children. Its appearance may exactly simulate that of measles or scarlatina, but it differs from these in disappearing in less than twenty-four hours, and in leaving no desquamation behind it.

The erythema that accompanies small-pox—*roseola variolosa*—appears generally on the second day of the disease, either as a diffuse redness of the whole integument, or as bright red spots which are seen first on the face and then on other parts of the body. It lasts from twelve to thirty-six hours, and disappears when the small-pox eruption begins to show itself. A special limited form of erythema has been observed on the second and third days of small-pox, extending from the hypogastrium down the front of the upper two-thirds of the thigh; the affected surface, when the legs are closed, having the form of a triangle the base of which is across the lower part of the abdomen. This surface remains almost or entirely free from the variolous pustules, and many of the cases in which it is present end fatally.

From the third to the eighteenth day after vaccination, small or large erythematous patches—*roseola vaccina*—are sometimes seen, generally on the arms, but also on other parts of the body. They usually disappear within twenty-four hours, and leave neither desquamation nor pigmentation.

The forms of erythema mentioned above cannot be considered as being in themselves specific varieties of disease, and pathologically consist in a temporary injection of the capillary blood-vessels of the skin. They are to be distinguished from the erythemata that run a distinct course, terminating in pigmentation and desqua-

ERYTHEMA (*ἔρυθρος*, red). **SYNON:** *Rose-
rash; Fr. Erythème; Ger. Hautrothe.*

DEFINITION.—A non-infective superficial inflammation of the skin, the essential characteristic of which is redness, which disappears on pressure by the finger, reappearing when the pressure is removed. The hue may vary from a bright rose to a dark blue red, it may or may not be accompanied by swelling; the part may be hotter than natural; and the appearance may present itself as spots, circumscribed or diffuse, or as wheals. It is sometimes attended by a sensation of slight burning or itching, but generally gives rise to no subjective symptoms. After it

nation, and in which the capillary injection is accompanied by exudation.

Idiopathic Erythema.—I *Erythema multiforme*.—This form of idiopathic erythema is most commonly seen in spring and autumn, and is distinguished by its location. It begins on the backs of the hands and feet, and frequently is found in these situations only. In some cases it extends upwards to the shoulders and hips, and in very rare cases is also found on the trunk.

The appearance consists in flattened papules from the size of a pea to that of a bean, of a dark blue or brown-red colour. They are surrounded on their first appearance by a red zone which soon disappears, and the border of the papule then stands out in fuller relief. The mildest form of this disease consists in papules which disappear after a few days—*erythema papulatum seu tuberculatum*. Instead of thus disappearing it may spread outwards from the edge, and flatten and become pale in the centre, thus forming a red ring, the condition being known as *erythema annulare*. While the first circle persists a second ring may form round it, and the circles may be constituted by small papules, forming the condition recognised as *erythema iris seu mammellatum*. Another stage may be reached by the enlarging circles meeting, and so forming segments of a circle, constituting the form known as *erythema gyratum seu marginatum*.

At any of these stages the eruption may disappear. The sequelae are slight pigmentation and desquamation.

The disease, whose different stages have received the different names above indicated has been designated, on account of the different forms under which it may be seen, *erythema exudativum multiforme*. It is accompanied by a slight feeling of burning or by very slight itching. Constitutional symptoms are only present exceptionally, and when the eruption is universal Hebra relates that in a woman who had what an eruption of *erythema gyratum* was on the skin, similar red rings were found in the small intestine. It is most common in adolescence, and is more frequent in males than in females.

II. Erythema nodosum.—This name is given to a disease characterised by the appearance on the skin, and chiefly on that of the lower extremities, of pale red hemispherical or oval swellings. These vary in size from that of a pea to that of a hen's egg, and are painful on pressure. Fever is sometimes present.

The swellings are at first pale red with a yellowish tinge, later dark red, and finally livid, after they disappear they leave behind them a yellow pigmentation similar to that which follows a contusion. The number of swellings may vary from a very few on the lower extremities to successive crops on different parts of the limbs and trunk. In the latter case the feverish symptoms are well-marked. The course of the disease is completed in two to four weeks. The swellings never suppurate, never itch, are always painful, and the redness never spreads to the adjoining skin. This variety can occur in combination with the previously described forms of *erythema multiforme*. It is a disease of child-

hood and adolescence, and is chiefly seen in females.

PROGNOSIS.—The prognosis of the special forms of erythema—*multiforme* and *nodosum*—is always favourable. These varieties seen in the course of other diseases do not modify the prognosis of the particular disease which each accompanies.

TREATMENT.—The treatment of erythema consists in palliating the attendant symptoms. Dusting with flour, or the application of spirit-lotion, should be employed when productive of a sense of comfort to the patient. In *erythema nodosum* warm applications of infusion of poppies or chamomile are soothing, while aperients, and, when fever is present, gentle diaphoretics may be given internally. In many such cases tonics, especially quinine, are required.

GEORGE THIN.

ESCHAROTICS (*εσχάρη*, a slough).

DEFINITION.—Escharotics are substances that completely destroy the tissues to which they are applied, and produce a slough. They are distinguished from other caustics simply by the greater intensity of their action.

ENUMERATION.—The chief escharotics are:—The hot iron, Sulphuric Acid, Nitric Acid, Potash, Chloride of Antimony, Chloride of Zinc, Acid Nitrate of Mercury, Bromine, Chromic Acid, and Lime. Weaker caustics are—Nitrate of Silver, Sulphate of Copper, Sulphate of Zinc, Iodine, Carbolic Acid, Arsenious Acid, Sulphide of Arsenic, and Dried Alum.

ACTION.—Escharotics combine with the tissues and destroy them. Around the part thus killed inflammation is set up, and the part is separated as a slough. Besides their local action these agents act reflexly on other parts of the body through the nerves of the region to which they are applied.

USES.—Escharotics are employed, first, to destroy the virus in, and the tissues around, a poisoned wound, and thus prevent the absorption of the poison, for example, in bites by snakes or rabid animals, or in cases of inoculation with syphilis, or with animal-poisons in dissection or post-mortem examinations. Secondly, they are used to destroy unhealthy tissue, such as exuberant granulations, and to remove excrescences and morbid growths, as warts, condylomata, naevi, polypi, hemorrhoids, and cancer. Thirdly, they are used to open abscesses, especially those of the liver. For this purpose caustic potash is usually employed. Lastly, by means of escharotics it is usual to establish ischæmia, and thus react beneficially on distant organs.

EVACUANTS (*evacuō*, I empty).—**DEFINITION.**—Medicines used to produce some evacuation from the body.

ENUMERATION.—The chief evacinants are:—Purgatives, Expectorants, Sinagogues, Emetics, Cholagogues, Purgatives, Diaphoretics, and Diuretics. See the several articles upon these subjects.

EXACERBATION (*exacerbo*, I make violent).—Increase in the severity of the symptoms of a disease.

EXANTHEMA, EXANTHEMATA.—(*ēx*, out, and *anthē*, I blossom).—SYNON · 1 r. *Exanthème*; Ger. *Ausschlag*

DEFINITION.—A rash or eruption on the skin.

The use of this term, once denoting any cutaneous eruption, is now restricted to the eruptive fevers called the *exanthemata*. Dermatologists discriminate the febrile rashes or exanthems of local or individual origin—urticaria, erythema, and roseola—from the true exanthemata, which are acute specific infectious diseases, namely, Typhus, Variola, Variella, Morbilla, Rotheln, Dengue, Scarlet fever, Typhoid or Enteric fever, and perhaps Erysipelas. In this article some leading features of these diseases will be shortly stated, and, as each of them will be found fully discussed under their several heads, it is only necessary further to notice certain less defined and regular eruptions associated with fever.

All the exanthemata are attended with fever and enlargement of the lymphatic glands.

Typhus.—The military rash appears suddenly on the fourth and fifth days of illness as a dull red mottling of irregular, persistent, non-elevated spots, the fever, high at the commencement, continues so after the rash is fully developed.

Typhoid.—In typhoid fever the small raised, rose-spots do not appear till the second week of fever; sparsely scattered on the trunk, they fade on pressure, disappearing in three or four days, while new spots arise.

Small-pox.—Marked fever of sudden ingress occurs two days before the raised eruption, sometimes a rose rash first appears, but the severe symptoms begin a full day before this and not more than two days before the characteristic spots appear. The cervical glands are enlarged.

Varicella.—The eruption begins on the first day of illness, the fever is often high and comes on suddenly, but enlarged cervical glands and spots nowhere are always to be found at the same time.

Measles.—Three days of fever and catarrh, with palpable enlargement of the cervical glands, precede the rash, there is then sudden increase of fever, subsiding while the rash is at its height.

Rotheln; Kneola sine catarrho.—The rash appears within a few hours of the first feeling of illness, which is slight and soon over. The rash is at first spotted rather than finely diffused. By the time it is fully out the fever has subsided, but the enlarged cervical glands which marked the ingress always remain to indicate a specific disease; fine desquamation rarely follows, and there is no albuminuria. Rotheln is invariably transmitted by contagion, the incubation being from two to three weeks; this long period of incubation causes the source of infection to be

often overlooked, and even the possibility of it to be denied, when carried to a family or school either an unnecessary alarm of measles is raised, or the next sufferer are said to have all drunk cold water together after being heated.

Dengue.—Widely-spread in Africa, the warmer parts of America, and both the Indies. Dengue may possibly be limited to hot climates, its presence with us is as yet undetermined. The rash is at first discrete, like that of measles, but follows soon after infection, and the increase in its general course is allied to scarlet fever.

Scarlet fever.—The finely diffused redness is found on the skin and in the mouth and throat often within a few hours of the sudden ingress of fever, the fever increases with the development of the rash, both persisting for several days. Often the throat is first complained of, the glands at the angle of the jaw are full and tender. Scarlatina is often declared three or four days after surgical operations. The skin is not swelled as in erysipelas, nor the redness so circumscribed, the throat also is redder, the cervical glands are enlarged in both.

Epidemic Roseola.—An epidemic roseola, having such relation to scarlet fever as rotheln to measles, has but slender claim to autonomy. Mild cases of scarlet fever often begin with a finely-diffused redness shortly after some feeling of faintness or giddiness, an incubation of from three days to a week is observed, sometimes albuminuria occurs as an early symptom. The finely-diffused rash enlarged cervical glands, and light sore throat even with very little elevation of temperature raise the suspicion of scarlet fever, should albuminuria follow or any shoddy desquamation of the hands and feet, no uncertainty remains. Scarlet fever so modified often spreads and gives rise to the severer forms of the disease when it has been called only rose rash or roseola; the use of these terms without a distinctive qualification always leaves a doubt as to the completeness and safety of the diagnosis.

Erythema comes nearest to these cases in appearance, so near as often to be spoken of as recurrent scarlet fever or erysipelas, but there is no enlargement of the cervical glands in erythema, and so little fever that the temperature of the reddened skin is barely elevated above the normal. Since Fuller's *Exanthematologia* this kind of flush passes under different names of roseola, according to the variousness in shape of the red patches, or the seasons of the year at which they occur.

Erythema nodosum is often preceded by slight fever for a day or two, this may reach 102°, but subsides as the red swellings appear, locally there is little or no elevation of temperature even when the tender part feels hot.

Exanthematous Roseola occurring in the course of other specific diseases is distinguished from the roseola which depends on nerve-irritation, caused, for example, by acrid ingesta, by the presence either of high fever, or of glandular enlargement, or of both, as when it precedes the true variolous eruption. During enteric fever this form of roseola may occur quite independently of the special lenticular rose-spots.

An eruption of this kind is not infrequent in the early stages of diphtheria, sometimes as a

diffused rash limited to certain parts of the chest and body, or as discrete spots on the limbs and back of the hands and feet. Influenza, and some forms of catarrh, winter 'colds,' or summer diarrhoea as noticed by Bateman, may begin with punctiform roseola on the back, shoulders, and chest, the cervical glands are perceptibly enlarged, though there may be little fever. In these cases it is not the roseola, but the specific disease on which it depends, that might, without proceutions, be communicated to others.

Syphilitic Roseola.—A special roseola marks the secondary stage of syphilis, in appearance it resembles the rash of measles, so does the *roseola ab ingratia* when produced by cubela, but this has neither fever nor glandular enlargement.

The absence of fever from the roseola after vaccination refers this form of eruption, like that occurring from dentition to the class of rashes from nerve-irritation. *Vaccinia* is itself an exanthem in the wider definition of the term, reproduced after a definite period of incubation by inoculating a special contagium. Wanting this character the different forms of herpes are excluded, though resulting from a general fibrile disturbance, though inconvertible, ecthyma and impetigo are local affections not belonging to the exanthemata. WILLIAM SQUIRE.

EXCITANTS (*excito*, I excite).—It seems hardly necessary to give any special consideration to this therapeutical class, as all that may be said on the subject ranges itself with greater propriety under the heading STIMULANTS. Stimulation is, in fact, a degree of excitement, and it is only when its effects are more vigorously pushed that we obtain that inebriation or exhilaration which is so commonly observed to follow the use of alcohol, ether, and the anaesthetic vapours. See STIMULANTS. ROBERT FARQUHARSON.

EXCITING CAUSE. See DISEASE, CAUSES OF.

EXCITO-MOTOR Disorders. See REFLEX DISORDERS.

EXCORIATION (*ex*, from, and *corium*, the skin).—The superficial destruction of a portion of the skin or mucous membrane.

EXERCISE.—**DEFINITION.**—In its widest and most correct signification, exercise is the setting in motion any active body, and when the term is used in a physiological connection, it may refer to the functional activity of any of the organs, whether muscular, nervous, nutritive, secretory, or reproductive. In this very comprehensive sense, the subject of Exercise includes a large portion both of hygiene and of therapeutics. The popular signification of Exercise is, however, much more limited than the preceding, having reference only to the muscles directly, and to the parts called into play through the same—especially the circulatory and respiratory systems.

Whether in its wider or in its narrower sense, exercise has several important relations to Medicine. 1. It is essential to the preservation of health (*see PERSONAL HEALTH*). 2. It has to be regarded as frequently associated with the causation of disease (*see DISEASE, CAUSES OF*). 3.

Exercise is a most rational and successful means of treatment in certain disorders and diseases (*see MOVEMENT, Therapeutics of*). 4. Exercise is often abused; and excessive indulgence in some forms of it gives rise to serious consequences. The present article will be devoted to the consideration of Exercise in the last-named aspect only, and the subject will be discussed according to the more limited and popular definition of the term.

Abuse of Exercise.—From the moment an infant is born until the end of life, exercise, duly apportioned to rest, is the normal state of existence, and whilst continued overstrain of any portion of the human machine is the forerunner of disease, so, on the other hand, is equally, if not more so, that want of exercise which induces wasting and degeneration.

PRINCIPLES.—Dr. Pirkes, in his *Practical Hygiene*, has given a very complete statement of the results of the investigations of himself and others on the changes effected by the stimulus of muscular exercise on the various organs and tissues of the body from which he has drawn the following conclusions:—

'The main effect of exercise is to increase the oxidation of carbon, perhaps also of hydrogen. It also eliminates water from the body, and this action continues as seen from Pettenkofer and Voit's experiments—for some time, after exercise the body is therefore poorer in water, especially of the blood, it increases the rapidity of circulation everywhere, as well as the pressure on the vessels, and therefore it causes in all organs a more rapid outflow of plasma and a more active absorption—in other words, a quicker renewal.

'In this way, also, it removes the product of their action which accumulates in organs; and restores the power of action to the various parts of the body. It increases the outflow of warmth from the body by increasing perspiration. It therefore strengthens all parts. It must be combined with increased supply both of nitrogen and carbon (the latter possibly in the form of fat), otherwise the absorption of oxygen, the molecular changes in the nitrogenous tissues, and the elimination of carbon, will be checked. There must also be an increased supply of salts, certainly of chloride of sodium, probably of potassium phosphate and chloride. There must be proper intervals of rest, or the store of oxygen, and of the material in the muscles, which is to be metamorphosed during contraction, cannot take place. The integrity and perfect freedom of action both of the heart and lungs is essential, otherwise neither absorption of oxygen, nor elimination of carbon, can go on, nor can the necessary increased supply of blood be supplied to the acting muscles without injury.'

The proper amount of exercise requisite for health is difficult to determine, in consequence of the varied constitutions of individuals. It may, however, be accepted that whilst in youth the great spirit of emulation tends to an overstrain of mind or body, as, life advances, one or other or both are liable to be allowed to pass into a state of unhealthy inactivity.

Since the recent more general practice of

gymnastics in this country, and the stimulus that has been given to aquatic exercises by our University competitions, great attention has been drawn to the effect of bodily exercise on health, and more especially with regard to the heart and lungs, these being the organs upon which its influence is most immediately exerted.

a. Prolonged and Excessive Exercise.—Of all exercises, rowing is the one which is generally accepted as the best variety to select if we are to endeavour by a consideration of its influence upon those who practise it to form an estimate of the effect of a continuous strain on the circulation and respiration, yet the difficulty of procuring trustworthy evidence on such a subject is extreme. Dr Morgan, in his *University Oars*, by collecting the various experiences of nearly all the men who rowed in the University races from 1829 to 1869, has obtained about the most accurate testimony available in regard to one aspect of the subject. These men are unanimous in their belief that they experienced no injury from the great strain they underwent in their youth. But it must be borne in mind that they were the picked athletes of their colleges, men with large frames and full chests, typical specimens of health, capable of undergoing very prolonged exertion with but passing fatigue, and to whom no permanent injury could be anticipated, after careful training, from an exceptional display of strength. Such evidence affords no clue to the effect of the strain imposed on the heart by the two hundred or more of each University, who annually use the utmost exertion to belong to the chosen few, and many of whom, unguided in their violent efforts to achieve success, have in after-life to pay the penalty of allowing mere feeling or spirit of emulation to overrule their reason.

b. Exercise under Unnatural Conditions.—But it is not only the case that exercise which is excessive or too prolonged proves highly deleterious; even a moderate amount of exercise under unnatural conditions may prove equally harmful. Thus the young soldier of light frame, with irritable palpitating heart, who has broken down in his preliminary training, is a marked and good example of the early injurious effect of overstrain of the heart, under the impediment caused by tight clothing and accoutrements to the free expansion of his chest. When at rest he feels perfectly well, and has little or no sensation of throbbing in his chest. So soon, however, as he puts on his tunic and accoutrements, and begins his drill, throbbing occurs with more or less violence, accompanied with a feeling of oppression, and with difficulty of breathing, and thus being followed by a sensation of faintness, sickness, or dizziness, he has to fall out of the ranks. At first the condition of the heart is one purely of functional disturbance, which, though rendering him unfit for the duties of a soldier, does not interfere with his gaining his livelihood as a civilian.

This functional derangement of the heart, which is readily shown by the diastolic in the sphygmographic tracing of the radial pulse when auscultation can detect little or no change in the heart-sounds, is frequently found in those

youths of delicate frame in our schools and colleges, who, breaking down in attempting feats of strength or in the preliminary training, experience no ill-effects in the ordinary avocations of after-life from that overstrain of heart which, if neglected, would be apt to lead to graver forms of heart-disease.

Whether it be by sudden or prolonged violent exertion, by rowing, or by running, or by the many other severe exercises of the body entailed by labour or pleasure, there can be no doubt that the heart and lungs have so times an inordinate amount of strain forced upon them, which in a state of health, or under favourable circumstances, they may reasonably be expected to bear with no more injury than temporary distress, and that this capability to bear strain is greatly enhanced by careful training.

It is customary for the healthy boy, however, owing to the character of his amusements, always to be in training, so far as his body is concerned, and with very little supervision he ought to suffer no harm from sudden and exceptional strains. But it is very different with men who have settled down into the real business of life, but who, during their nominal periods of rest from their daily labours, undertake violent exercises without any preliminary training and thus throw such an unexpected strain on the heart and great blood-vessels, that instead of more functional disturbance as in early life, they sow the seeds of organic disease. Such being the case, how much more injurious must sudden overstrain be to a heart already weakened by disease? There is often found amongst men a great aversion to having their hearts examined, and when disease is discovered it is sometimes considered of questionable advantage to inform the sufferer of his condition; but this is a mistake for from want of knowledge of his state he may, by unnecessary strain rapidly aggravate it, and thus shorten a life which might otherwise have been much prolonged.

The purport of these observations is thus to point out that—Firstly, whereas exercise is necessary to preserve our bodies in a proper state of healthy activity, its tendency, when carried to extremes is to set up organic lesions. Secondly, that as in some athletic competitions a very great strain is thrown upon the thoracic organs, it is essential that no boys of delicate frame should be allowed to take part in them, or in the preliminary training, excepting under careful medical supervision. And, thirdly, that in manhood no violent competition should be undertaken, which would throw a great strain upon the thoracic organs, without their being previously examined and pronounced sound, nor until their full powers have been brought into play by careful preliminary training.

A. B. R. MYERS.

EXFOLIATION (ex, from, and folium, a leaf).—The separation of a portion of dead bone or cartilage from the living tissue, in the form of layers (see BONE, Diseases of). The term is also applied to the separation of a false membrane which has been mistaken for the whole mucous lining of the bladder or uterus. See BLANDER, Diseases of.

EXHAUSTION (ex, from, and *haurio*, I draw out).

DEFINITION.—Exhaustion is a phenomenon which all irritable tissues can be made to manifest, and consists in a failure to respond to stimulation. Exhaustion of muscle and nerve is brought about by excessive, quickly repeated, or continuous stimulation. It is favoured by cutting off, or by asalteration in the quality of, the blood-supply; by previous insufficient exercise of function; by exposure to extremes of temperature; by an insufficient supply of oxygen; by an excessive supply of carbonic acid; and by exposure to certain toxic agents. These facts, which have been established by physiological experiments, are fully borne out by clinical experience.

Exhaustion may be *general* or *local*.

1 **General Exhaustion**.—General exhaustion is brought about by over-work, whether physical or mental, and especially by unrelenting and monotonous duties which keep the same paths of action in a state of constant activity. It is not often, if ever, that any permanent harm is produced in a healthy man by mere physical labour, however great, but excessive mental labour, especially if it be monotonous, is certainly capable of permanently damaging the nervous tissues. When in addition to hard mental work, which is performed voluntarily, some constant stimulus, which cannot be arrested, unceasingly works upon the brain, exhaustion quickly results, as when, for example, a man who is harassed by trying to earn sufficient for his family meets with some shock to his nervous system (such as a railway accident, the sudden death of a dear relative, or a severe money loss) which haunts him like a spectre day and night, robs him of his rest, and deprives him of his appetite. General exhaustion is favoured by all conditions which give rise to *anæmia* or faulty nutrition, such as hæmorrhage, prolonged pyrexia, inadequate diet, persistent morbid discharges, or venereal excess, by the retention in the tissues of the products of their activity, which is favoured by working in a foul atmosphere, or by derangement of the excreting functions, by exposure to extremes of temperature, and by a previous condition of excessive slothfulness. General exhaustion may occasionally be suddenly induced by physical causes, such as a severe injury (collapse from shock), or psychical causes, such as fright.

SYMPTOMS.—The symptoms of general exhaustion are:—1. Loss of sleeping power, persistent dreaming, talking in the sleep and somnambulism. The patient may wake in the morning feeling totally unrefreshed. 2. Inequity for work, and inability to seriously apply the mind to one subject for any length of time. 3. Headache, and a feeling of oppression in the head. 4. Languor and general lassitude. 5. A rapid feeble pulse. 6. An anxious expression of face; and (as stated by Dr. George Johnson) a contracted and sluggish pupil. In addition to these we may get tremor, delirium, hypochondriasis, hysteria, epilepsy, chorea, mania, and general paralysis. Two instances have come within the writer's knowledge of transient hemiplegic symptoms having been induced by excessive application to literary

work. The digestion is often deranged, and functional disturbance of the heart is common. Occasionally the urine is altered in quality, and may contain alkaline phosphates or sugar. More rarely it manifests excessive acidity.

2. **Local Exhaustion.**—Local exhaustion is the result of excessive local stimulation, and it is particularly liable to occur as a prominent symptom in patients who are suffering from general exhaustion. The loss of power in the rectum which results from the excessive use of purgatives, the failure of the uterus in cases of protracted labour, and the failure of the voluntary muscles which occurs in those professional ailments of which 'writer's cramp' is the type, may be taken as examples of local exhaustion.

TREATMENT.—In the treatment of exhaustion the indications are to lighten the labour, and obtain rest. In cases of general exhaustion it is often advisable to administer narcotics, such as opium, hydate of chloral, or bromide of potassium, and it will be generally found that, when once refreshing sleep has been established, the more aggravated symptoms will subside. Fresh air and a good diet are most necessary. Stimulants must be used with great caution, for it is clearly not desirable to goad the exhausted organs into further action, although it may be necessary to employ stimulants to give temporary power while the faculty of sleeping is being re-established. All causes of *anæmia* must be removed. When recovery is established, the patient must be encouraged to relieve the monotony of his life by some pursuit which should be, as it were, the complement of his ordinary occupation. Thus the head-worker should endeavour to amuse himself in his leisure hours by gentle out-door exercise, by music or painting, or by practicing some handicraft. See *DEBILITY*, and *FATIGUE*.

G. V. POORE.

EXOPHTHALOS (*exo*, beyond, and *ophthalmos*, the eye.) A term applied to umbilical hernia. See *HERNIA*.

EXOPHTHALMIC GOÏTRE (*exo*, out, and *ophthalmos*, the eye, and *goître*).—**SYNONYMS:** Graves' Disease; Basedow's Disease, Fr. *Maladie de Graves, Goître exophtalmique*, Ger. *Glotz-ang-kropf, Basedow'sche Krankheit*.

DEFINITION.—Enlargement with vascular turgescence of the thyroid gland, accompanied by protrusion of the eyeballs, breathlessness, palpitation, and *anæmia*.

ÆTIOLOGY.—This disease is comparatively rare among men. It occurs most frequently in women between the ages of twenty and thirty, but is met with amongst older persons. Patients suffering from it often belong to the so-called nervous diathesis. Its occurrence is often preceded by menstrual disturbance and *anæmia*. Sometimes no exciting cause can be discovered, but in many cases it comes on after violent nervous excitement.

SYMPTOMS.—Before exophthalmic goitre makes its appearance, alterations in temper are frequently observed, the patient becoming irritable and depressed. Functional disturbances of the circulation and heart occur at frequent intervals, the heart palpitating, the face flushing, and a

sensation of fulness being felt in the head, eyes, and throat. The pulsation increases, the eyes become prominent, and a visible swelling appears over the thyroid gland. The eyes are lustrous and projecting, and there is frequently a slight loss of co-ordination between their movements and those of the eyelids, so that when the eyes are quickly cast down the eyelids follow them so slowly that a white ring of sclerotic may be noticed between the iris and the lower margin of the upper eyelid. Usually there is no disturbance of vision. The exophthalmia is most marked during emotional excitement and at the menstrual period and at these times the patient suffers from an increased feeling of fulness in the eyeballs. Sometimes the projection of the eyeballs is so great that the lids do not perfectly cover them, and inflammation and ulceration may consequently occur. The thyroid is generally unequally enlarged. Its size varies from time to time, increasing like the protrusion of the eyeballs, with emotion. It is soft and elastic, and pulsates, so that it has sometimes been mistaken for aneurism. The pulsation of the heart is generally noticed before either the exophthalmos or enlargement of the thyroid, and is the first symptom to attract the patient's attention. It is increased by emotion or exertion, and the violent cardiac action frequently produces a prominence of the precordial region. The cardiac pulsations are rapid and sometimes irregular. The cardiac sounds are loud, and a soft, systolic bellows-murmur is frequently audible at the base, and in the large arteries. The carotids are sometimes, but not always, dilated. The circulation appears to be rapid, the veins filling quickly when emptied, and pulsation being felt even in small arteries. The temperature is frequently high. There is a feeling of general debility. The digestion is sometimes normal, at other times the appetite is diminished or capricious, and diarrhoea may occur. The swelling of the neck may give rise to a feeling of difficulty of breathing, and the voice sometimes becomes altered and hoarse, or may be lost entirely. The course of the disease varies considerably, it may sometimes go on increasing for several months, then it becomes stationary for one or two years, and afterwards begins to decline. The temper improves, the appetite increases, and menstruation frequently is re-established. The pulsation, enlargement of the thyroid, and prominence of the eyes gradually diminish, although they rarely disappear completely. Death may occur from intercurrent disease, from organic cardiac lesions, or from gradual wasting. Danger is also said to arise from pressure on the trachea by the enlarged thyroid.

PATHOLOGY.—The protrusion of the eyeballs is due either to dilatation of the vessels in the orbit, or to contraction of the involuntary muscular fibres in the orbital membrane which covers the spheno-maxillary fissure, or possibly to both causes combined. The enlargement of the thyroid is due to dilatation of the vessels of the gland. After the disease has lasted some time, increased formation of tissue in the thyroid gland may occur. Pulsation of the heart is probably due to stimulation of the accelerating cardiac nerves, and this as well as the alteration in the nerves

of the orbit and thyroid, has been ascribed to disease of the lower cervical sympathetic ganglia, in which increased connective tissue and diminution of ganglionic cells have been observed.

DIAGNOSIS.—When the three leading symptoms are present, it is impossible to confound exophthalmic goitre with any other disease. The enlargement of the thyroid is distinguished in this disease from that of cystic goitre by its greater elasticity, by its paroxysmal enlargement, and by its pulsation. The exophthalmos is distinguished from prominence due to cardiac disease by the lustrous appearance of the eye, from hydrophthalmia by the natural condition of the pupil, and from the prominence which may occur in myopia by the vision being natural, and by the paroxysmal increase of the prominence in exophthalmic goitre.

PROGNOSIS.—This must be guarded, the disease not being very amenable to treatment, and very rarely disappearing altogether, although after continuing for some years it may gradually improve.

TREATMENT.—The treatment of exophthalmic goitre chiefly consists in securing fresh air, gentle exercise, the avoidance of the least fatigue or emotional disturbance, and careful diet. Iron is sometimes useful, the milder forms, such as the tartarated iron or citrate of iron and ammonia, being preferable to the more powerful preparations. Quinine, alone or in combination with digitalis—and perhaps with belladonna—often produces good results. Aloes and nuxvom may be employed to keep the bowels open. Galvanism to the neck has sometimes been productive of benefit, one pole being placed in the nape of the neck and the other over the sides of the thyroid tumour. When the eyeballs are so prominent as to become liable to inflammation and ulceration, care must be taken, by means of a shade, to protect them from irritation, and if this should prove unavailing, the inflammation must be treated by appropriate remedies.

T. LAUDER BRUNTON.

EXOSTOSIS (*Exo*, out of, and *ostion*, a bone).—A bony outgrowth from any part of the skeleton. See *PAGE*, Diseases of.

EXPECTANT ATTENTION—An important mental state. See *MESMERISM*.

EXPECTORANTS (*ex*, out of, and *pectus*, the chest).—*SYNON.*—*Fr.* *Expectorants*; *Ger.* *Anschnittsfördernde Mittel*.

DEFINITION.—Medicines which facilitate the removal of secretions from the air-passages.

ENUMERATION.—The leading expectorants are:—(1) *Ipecacuanha*, *Antimony*, and *Iodide of Potassium*; *Chloride of Potassium*, *Sodium*, and *Ammonium*; and *Inhalation of Steam*. (2) *Squill*, *Senega*, *Benzoin*, *Benzoic Acid*, *Benzonate of Ammonia*, *Nuxvom*, *Storax*, *Balsam of Tolu*, *Balsam of Peru*, *Ammoniacum*, *Galliacum*, *Assa-fetida*, *Anise*, *Fennel*, *Larch Bark*, *Tar*, *Copiba*, *Vapour of Chlorine*, *Iodine*, *Ammonia*, *Cressote*, and *Carbolic Acid*. (3) *Ammonia*, *Carbonate of Ammonia*, *Strychnia*, *Nux Vomica*, and *Belladonna*.

ACTION.—The mode of action of expectorants

is not well understood, and any explanation of it in the present state of our knowledge can only be regarded as provisional. Expectorants may be divided into two classes:—1 Those which modify the nature of the secretions from the respiratory passages, and, 2 those which modify the respiratory movements by which the secretions are expelled. In considering the mode of action of the first class it must be remembered that the secretions from the respiratory passages depend, like many other secretions, on two factors, the direct influence of the *nerves* upon the secreting structures, and the amount of blood supplied to them. Each of these two factors may be influenced to a different extent by various drugs. As has already been said, the exact action of each cannot be determined at present, but the first class of expectorants may be subdivided into two divisions which are distinguished in the foregoing nomenclature as A and B. The division A rather diminish than increase the activity of the circulation, and are therefore called *sedative* expectorants. The division B somewhat increase the circulation, and are called *stimulating* expectorants. Those comprised under C stimulate the respiratory centre in the medulla oblongata, and increase the respiratory movements.

Uses.—Sedative expectorants (class A) are useful when there is congestion of the respiratory passages, with very acute, tough expectoration as in commencing bronchitis. In such circumstances, when dry rales are heard abundantly, with few or no moist rales, the patient often coughs until quite exhausted, bringing up scarcely anything. The administration of sedative expectorants renders the secretion from the respiratory passages more fluid, abundant, and easy to expectorate. When these expectorants do not succeed in ordinary doses, their action may be much assisted by the administration of a purgative, or, still better, by giving either ipecacuanha or tartar emetic in such a large dose as to produce sickness and vomiting. When the distress of the patient is great, the abstraction of a small quantity of blood by cupping or by venesection may give great relief. The inhalation of steam alone is also beneficial, and the air of the patient's chamber should be kept warm and moist. Stimulating expectorants (class B) do more harm than good when administered in the conditions just described, but are beneficial when the acute symptoms have passed off. When this is the case, but the expectoration is tough and somewhat scanty, squill is a useful expectorant, but when the expectoration is abundant, benzoin, balsams or ammoniacum are preferable. In chronic bronchitis, inhalations of ammonia, or of no iodine, creosote, carbolic acid, or any acid are useful. When the expectoration is fetid, chlorine, iodine, and carbolic acid inhalations are best. The expectorants which act on the respiratory movements (class C) are useful in cases of debility, as they stimulate the respiratory nervous centre in the medulla oblongata, as well as assist the failing circulation. They may be advantageously combined with stimulating expectorants, such as squill or benzoin, according to the nature of the secretion.

T. J. ALPHEA BRUNTON.

EXPECTORATION (ex, out of, and pectus, the chest).

DEFINITION.—This word, which strictly means the act of expelling anything from the chest, is usually applied to the matter so expelled, which is also called *sputum* or *phlegm*.

THE ACT OF EXPIRATION.—The smaller bronchial tubes are kept free from obstruction by the action of ciliated epithelium. The area of the smaller tubes being greater than that of their trunks, the air passes more forcibly through the latter, and so tends, even in natural breathing, to carry speedily away any accumulated secretion. The forcible acts of coughing (see *Cough*) and 'hawking' increase the natural force and fulness of the expiratory effort, and clear the air-passages, the repeated closure of the glottis in coughing increases still further the explosive effect, by causing the air to escape in sudden jerks. If, in consequence of laryngeal disease, the glottis cannot close, the act of expiration becomes painful and difficult. Efforts at expiration are also laboured and futile if, in consequence of emphysema or muscular weakness, the power to take a deep inspiration is lost.

Inability to expectorate is often the immediate cause of death, the 'suffocative catarrh' of the dying being another name for accumulation of phlegm, which the patient is powerless to remove. By teaching the patient 'how to expectorate,' by the administration of a timely stimulant or a quickly acting emetic, or by change of posture, life may in such a case be prolonged. Should the sufferer be allowed to get flustered, the breathing becomes more and more shallow, and deep inspiration and free expectoration are impossible. If, however, the patient can be induced to breathe calmly and deeply, to assume a more easy posture, and to swallow a solution of ammonia with ether, the breathing gradually becomes less shallow and rapid, air enters the deeper parts of the lung, and power is gained to evacuate the accumulated secretion. The act of expectoration is, as a rule, most easy in that posture in which respiration is most free. Sometimes, when the secretion comes mainly from one lung, the aid of gravitation may be called in to empty the obstructed tubes.

CHARACTERS AND VARIETIES.—Before auscultation was practised, diagnosis was often based on the character of the expectoration, unvaryingly of importance having been attached to the distinction between pus and mucus, on the assumption that pus was diagnostic of phthisis. At the present time we are apt to lose much by falling into the opposite error.

In health, the secretion from the mucous membrane of the air-tubes is a transparent, colourless, slightly glutinous liquid, like thin mucus; it contains *mucus*, a very large quantity of saline matter, and water.

The saline matter is abundant in the transparent viscid expectoration, deficient in the opaque and less tenacious kind, least in that which is actually purulent.

The ordinary mucous secretion is increased in quantity and viscosity as a result of simple catarrhal inflammation of the bronchial membrane. When bronchitis has existed for some days, a croup occurs in the character of the secretion.

instead of being transparent and viscid, it becomes semi-transparent and then opaque, the colour changing to a yellow or greenish hue.

The sputum becomes frothy from the admixture of air; and rusty or prune-juice-coloured if the inflammatory action extends to the ultimate bronchial ramifications, and is of so intense a kind as to allow of oozing from the capillary vessels.

Fibrous moulds of the bronchial tubes, or chalky masses consisting of inspissated and calcified alveolar matter, are not unfrequently expectorated.

The dark grey or blackish stain often seen in expectoration may be derived from carbon in the atmosphere, or, if it fade on the addition of nitric acid, it may be due to pulmonary pigment formed under slight irritation.

The expectoration may afford important aid in diagnosis, as may be illustrated by the following examples:—If a person with severe chest-complaint coughs frequently and spits only frothy salivary fluid, we may suspect pleurisy. If the fluid is glairy like white of egg, we may suspect bronchitis. If it has a rusty tinge and resembles thick gum-water coloured with blood, we are not likely to err in recording pneumonia. If there is a sudden gush of fetid pus we may diagnose abscess in the lung or an empyema.

Purulent expectoration may occur in bronchitis as well as in phthisis, but if long-continued, and unaccompanied by distinct rhonchus, it almost always comes from a vomica.

In phthisis the sputum is at first salivary or frothy, the result of irritation, then viscous, indicative of more confirmed affection of the mucous membrane, and subsequently dotted and streaked with blood. Whitish opaque spots, giving a pearly aspect to the expectoration, next appear; these enlarge, become flocculent and ultimately nummular, being inspissated and moulded in a cavity. As the disease advances and involves both lungs, the expectoration is entirely purulent, and shortly before death is often surrounded with a pinkish halo. On placing under the microscope one of the small pearly points described, masses consisting of several air-cells choked with granules, or mere fragments of elastic tissue may occasionally be seen. By the addition of acetic acid the sputa may be rendered transparent, and the elastic tissue is then, if present, more certainly detected, but practically the experienced eye is the best guide in the selection of those small pin-head fleecy of expectoration, in which the microscopic particles of lung-tissue are to be detected.

The microscope may be also helpful by indicating, from the character of the cells, the part of the respiratory tract involved, and the degree of disease existing.

TREATMENT.—In treatment, much may be gained by study of the expectoration. The cough may often be relieved, and the dyspnoea and other symptoms removed, by effecting an alteration in the nature of the secretion.

If by the frothy character of the sputa contagious disorder is indicated, this may be met by the application of warm poultices, turpentine stupes, or hot flannels externally; and by such means as are calculated to reduce fever and irritability, namely, the administration of saline

with antimony or aconite. If the expectoration is too viscid and glutinous for easy removal, lemon-juice, liquor potassæ, soda, or various inhalations give relief, by lessening the tenacity of the secretion; or the change from tenacious and transparent to opaque less adhesive secretion may be hastened by giving iodide of potassium with a few drops of antimonial wine.

When mucopurulent secretion is established and shows no sign of diminution, the use of senega, and of the gum-resins is indicated, while benzoin, tolu, and copalva are also of value. Acetic or tannic acid, given in small and frequently repeated doses, reduces the quantity of secretion.

When the combined glairy and mucopurulent condition of the expectoration and other symptoms give evidence of bronchitis of an established kind, associated with gout or aluminous torpor, a combination of calomel with antimony and gamboge (as in Plummer's pill) is of the greatest service, but this treatment needs perseverance, discrimination, and watchfulness. The morbid surface may at the same time be medicated by the inhalation of tar, creosote, or oil of juniper, until, with the improvement of the general health, under cod-liver oil and iron, the evil is entirely removed.

E. SYMES THOMPSON.

EXPOSURE, Effects of.—Were the term 'exposure' to be taken in its widest significance, it might fairly assume to include a range of subjects only bounded by the limits of practical medicine. Infection naturally implies exposure to some contagious influence, poisonous gases, or malarious or other unhealthy emanations, bearing in their train a formidable sequence of ill results. Many of the disorders which impair our comfort and shorten our lives may, in short, be traced, in some degree, to exposure of some kind, to an excess of heat or of cold, to a variety of complicated reactions, arising, in whole or in part, from unnatural impressions made on the physiological processes of life by various external agencies. Any study of our subject, however from this extended point of view, would clearly be out of place here, and effects of extreme elevation and depression of temperature will be fully considered elsewhere, so that exposure in the sense in which it will be treated here, may be narrowed down to the results which ensue when persons of average constitution-power are submitted, for a longer or shorter time, to the influence of ordinary cold, or wet, or damp. Now, it is an old saying that if five or six people, of either sex, suffer shipwreck, or are wet through, or excessively chilled by moist cold, each will probably suffer in some different way. One may altogether escape, and not experience inconvenience of any kind; a second may 'catch'—as the popular expression puts it—a sore throat, or a 'bad cold'; whilst a third may be seized with pneumonia, and a fourth with rheumatic fever.

Individual constitution or peculiarity of system partly explains these differences, and the familiar term of a 'weak point somewhere,' if not conveying much impression of scientific accuracy, is right so far in showing that the internal congestion caused by sudden contraction of cutaneous arteries is most naturally directed to that organ

whose vessels have been weakened by previous inflammation. If the patient, therefore, have previously suffered from tonsillitis, or bronchial congestion, or rheumatism, he will be predisposed to a recurrence of the same affection on a renewal of the exciting cause. If, again, from sedentary occupation and over-indulgence in nitrogenous food, his blood be overcharged with the products of retrograde metamorphosis or of imperfect assimilation, it only needs the clearance of the eliminatory agency of the skin, to provoke the irritation of internal organs, and to induce an attack of gout or rheumatism, or an acute inflammation of kidneys or liver. The effects of exposure, even in this limited sense, are thus tolerably various both in extent and in degree, and may be studied on a large scale during our greater campaigns, and in lesser degree during the ordinary autumn manoeuvres, when the weather happens to be unfavourable. Here, however, everything injurious is minimised by the healthy condition of the men, their good clothing and food, and the enforced regularity of habits, which prevent, in great measure, one of the most fertile causes of damage from exposure. It is now well known that nothing tends so seriously to impair the power of bearing either extreme of temperature as the excessive indulgence in strong drink, so that in treating anyone who has been exposed to the influence of cold and wet, we must not forget to take also into account the probable combination of the depressing effects of alcohol on the nervous system. Illustrations of this must be familiar to all and we must all have met with numerous cases in which tramps or other persons with weakened bodily vigour have been brought into our hospitals, suffering from the effects of exposure in various degrees.

TREATMENT.—In seeking to remedy the effects just described, it will be found that some of the cases will recover under the influence of warmth and good food, and the generally invigorating effects of careful nursing, whilst others, on the other hand, may succumb to the rapidly destructive tendencies of acute disease, or to the slower pathological processes of chronic lung or kidney degeneration. In the treatment, therefore, of such cases, we must not only add to the genial influences of home or hospital care such special drugs as the varied development of symptoms may require, but we must carefully take into account the occurrence of various serious or profoundly disorganising complicating causes. Thus if our patient has been found in an insensible state, we may reasonably suspect apoplexy or alcoholic or narcotic poisoning, and act accordingly. And only when all such suspicion is finally removed can we rest on our oars, and confine our attention to the immediate effects which follow exposure of the kind indicated above. Warmth, rest, and the regulated use of stimulants and food will now be indicated, and must be employed, with all the precautions suggested by the ordinary principles of therapeutics, and common sense.

ROBERT FARQUHARSON.

EMBAUGUINE (*ex*, without, and *anguis*, blood).—Deprived more or less of blood.—Blood-

less. Sometimes used synonymously with *anæmia*. See *ANEMIA*.

EXTRA-UTERINE PREGNANCY—See *PREGNANCY*, Disorders of.

EXTRAVASATION (*extra*, without, and *vasa*, vessels).—*SYNON.* Fr. *Extravasation*; Ger. *Extravasat*.

DEFINITION.—Extravasation is the escape of any of the fluids of the body, normal or abnormal, from the vessel, cavity, or canal that naturally contains it, and its diffusion into the surrounding tissues. The result of the effusion is also called an extravasation. Extravasation is the effect of rupture or perforation of the walls of a hollow organ, and may therefore be due to injury, to weakness of the parietal structures, to morbid conditions of the blood, or to increase of internal pressure. See *PERFUSIONS* AND *REPERFUSION*.

The fluids most frequently found extravasated are blood, urine, bile, the contents of the alimentary canal, and certain constituents of morbid growths and fluid collections. The present observations will apply chiefly to extravasation of blood.

Extravasation of Blood.—The blood is peculiarly liable to extravasation, the vessels being universally distributed, much exposed to injury, and subject also to a constant pressure from within, which may be suddenly and greatly increased. Any portion of the circulatory system may give way either the heart, as in fatty degeneration, the arteries, as in aneurism; the capillaries, as in pulmonary hæmorrhage; and the veins, as in the subcutaneous rupture of a varix.

When the effusion takes place into one of the serous sacs, it forms a collection of blood, variously named *hæmothorax*, *hæmatocoele*, &c. If the subcutaneous, submucous, or other connective tissue, or the substance of an organ be invaded, the effused blood finds its way between the elementary textures, separating and compressing them, and there are formed what are described simply as *extravasations* of blood, or more definitely, according to their extent, as *parechymatous* or *interstitial hæmorrhages* or *apoplexies*, *effusions*, *ecchymoses*, *petechiæ*, or *ulceræ*. The seat of effusion appears of the colour of blood or its derivatives, but if much below the surface, the extravasation may not be visible for some days, after which time it appears of a bluish, greenish, or yellowish hue. The extravasated blood generally coagulates; the fibrin and albuminous substances are absorbed; and the products of decomposition of hæmoglobin, which are much more slowly removed, give rise to the discolourations. Much less frequently the effused blood becomes encapsuled, forming a *hæmatoma* or *blood-cyst*. In other cases it decomposes, and sets up gangrene around, or inflammation of the nature of severe cellulitis, which may end in ulceration of the surface. When the blood is forced between the coats of the perforated vessel, there is formed what is called a *dissecting aneurism*. If the extravasated blood escape from the surface of the skin or mucous membranes, one term of *hæmorrhage* or a *bleed; flux* is the result.

The symptoms of extravasation of blood are so various that they cannot be stated in general terms. If extensive and affecting vital parts, the effusion may be attended by shock, syncope, or death; and it may lead to constitutional disturbance in many forms. Laceration is not common unless the extravasation be severe. The pressure of the effused blood upon the vessels, nerves, and muscles of the part, for example in a limb, may produce paralysis, disturbance of sensibility, oedema, loss of temperature, and even gangrene. As a rule however, extravasations of blood are very limited in size, give rise of themselves to no serious symptoms, and readily disappear by absorption.

J. MITCHELL BRUCE.

EXTROVERSION (*extra*, outwards, and *verso*, I turn) — The eversion or turning inside-out of a part, as the eyelids or bladder. In the bladder, extroversion is associated with that condition, usually congenital, in which the anterior wall of this organ and of the abdomen are deficient, and its posterior wall projects through the opening thus formed.

EXUDATION (*exudo* I sweat) — The process by which certain of the elements of the blood pass through the walls of the blood-vessels into the surrounding tissues, as in inflammation. It also indicates the products of the process when they are of a fibrous or coagulable character. See INFLAMMATION.

EXUDATION-CORPUSCLES The cells found in inflammatory products, whatever may be their origin. See INFLAMMATION.

EYE, and its Appendages, Diseases of. — It will be most convenient to arrange the consideration of the diseases of the eye according to the anatomical order of the structures affected, namely:—I. Diseases of the Conjunctiva, II. Diseases of the Cornea, III. Diseases of the Sclerotic, IV. Diseases of the Iris, V. Diseases of the Crystalline Lens, VI. Glaucoma, VII. Diseases of the Optic Nerve and Retina, VIII. Diseases of the Choroid, IX. Diseases of the Vitreous Body, and X. Diseases of the Eyelids.¹

I. Diseases of the Conjunctiva.

1. **Inflammation.** **SYNON:** Conjunctivitis — The conjunctiva is exceedingly liable to inflammation, and its inflammations are commonly arranged in groups, which are sufficiently distinct in their typical examples, but are not separated by any definite boundary lines.

In their earlier stages inflammations of the conjunctiva possess many characters in common. They are all attended by the four signs of inflammation—heat, redness, swelling, and pain, although both the heat and the swelling are usually kept within limits by the discharge, which is often free, sometimes profuse, at first mucous, afterwards muco-purulent or truly purulent in character. If, however, the exudation be of a firmer consistence than usual, it not only produces a superficial discharge, but distends the meshes of the sub-mucous tissue, elevates the conjunctiva from the sclerotic, and causes it to

overlap the corneal margin as a swollen ridge; a condition which is known as *chemosis*. The redness depends, of course, on the degree of the congestion, which may or may not be sufficient to obliterate the intervascular meshes and to produce an uniform colour, and the pain is not severe except in cases of very dense sub-conjunctival swelling from other forms of inflammation, that of the conjunctiva is distinguished by certain negative characters. Unless as a result of secondary changes or as a mechanical effect of the presence of a film of turbid secretion the transparency of the cornea is not affected, and the acuteness of vision is not impaired. The congestion is limited to the conjunctiva and the distended vessels can be emptied for a moment by pressure through the lower lid, so as to reveal a glimpse of the white sclerotic underneath.

In most cases conjunctivitis is an unimportant affection but in its more severe forms it is attended by two distinct sources of danger. During its acute stage it may produce partial or complete necrosis of the cornea leading to great impairment of sight and not seldom to blindness, and when chronic it often occasions great hypertrophy of the papillae of the portion of the membrane which lines the lids. These papillae may even become converted into shaggy or warty excrescences which mechanically irritate the corneal surface and cause the development of vessels beneath its epithelium. In time the papillae dwindle and the effusion round about them contracts, thus rendering the tarsal cartilages (especially that of the upper lid) recurved, and bringing the eye to rest upon the surface of the eyelid. Great distress and permanent impairment of vision may be thus occasioned, and the progress of the contraction may be so slow as to deprive it of any manifest connection with the inflammation in which it had its origin.

The chief varieties of conjunctivitis are:—(a) *infantile*, (b) *simple or catarrhal*, (c) *contagious*, and (d) *diphtheritic*.

(a) *Infantile Conjunctivitis.* **SYNON.** *Ophthalmia neonatorum*.

ÆTIOLOGY and SYMPTOMS.—Infantile conjunctivitis is probably due, in most cases, to direct inoculation with vaginal secretion. It usually commences on or about the third day after birth, and passes rapidly into the purulent form. It is attended by considerable puffing swelling of the lids, and by profuse thick discharge, which soon dries upon the tarsal margins, and often causes them to cohere. If neglected or improperly treated, the disease often leads to sloughing of the cornea, but it may always be cured if it is seen while the cornea is still bright.

TREATMENT.—The treatment required is to wash away the discharge carefully and frequently, to apply an astringent lotion (the best is a solution of 2 grains of nitrate of silver to an ounce of distilled water) to the conjunctival surface every four hours, or less frequently when improvement is established, and to anoint the edges of the lids with simple ointment to prevent their agglutination. In cases of inherited syphilis mercurial inunction should be prescribed, the infant's food must be carefully regulated if it is brought up by hand, and if it is very feeble it may

¹ See also **VARIOUS Disorders of:** OPTHALMOLOGY; and OPTHALMOLOGY: A MANUAL.

take a little cod-liver oil, combined in an emulsion with two-minim doses of liquor cinchonæ. Where the mother's milk fails, it is often desirable to obtain a wet-nurse, but the local treatment is that which is chiefly important, and upon which, in most cases, entire reliance may be placed.

(b) *Simple or Catarrhal Conjunctivitis.*

ÆTIOLOGY AND SYMPTOMS—This form of conjunctivitis is usually due to exposure to cold or to some chemical or mechanical irritant. Its most distinctive character is that the discharge is chiefly mucous, and has not much tendency to become purulent.

TREATMENT—In every case the surface of the eyeball and the lining membrane of the lids, should be carefully examined for any foreign body which may be the cause of the trouble, and if such should be found and removed, there will seldom be need for further treatment. If there is no foreign body the 2-grain solution of nitrate of silver may be placed within the conjunctival sac, by means of a quill or dropping bottle, every two or three hours, and speedy recovery will usually be the result. During the treatment the eyes should have functional rest, and should be sheltered from external cold, from dust, or from glare.

(c) *Contagious Conjunctivitis.* **SYNONYMS**—Purulent Ophthalmum.

In this form the discharge rapidly assumes a purulent character. This may happen when the simple form is aggravated by the state of the patient or by accidental circumstances, or when the disease is produced by inoculation with the discharge from a similar case or with contagious pus from the urethral or vaginal mucous membrane. The state of the patient which is most likely to promote the development of the contagious form is that in which the conjunctiva is beset with the granular semi-transparent bodies, formed by aggregations of lymph-corpuscles, which are known as 'magnogranula' or follicular granulations. These bodies are commonly present in the eyelids of persons (especially of young persons) who are crowded together under insanitary conditions of living as in barracks, camps, or badly regulated schools, and their presence renders the conjunctivitis of simple irritation prone to assume a purulent character. It is impossible to say how soon the discharge of conjunctivitis becomes contagious, or capable of reproducing the disease in others, but its activity in this respect seems to bear some proportion to the intensity of the inflammation which produces it, and the activity of gonorrhœal pus is probably greater than that of any conjunctival product. In the more intense forms of purulent ophthalmia there is great swelling of the lids and of the ocular conjunctiva, early chemosis, and a tendency to speedy sloughing of the cornea, while the milder forms pass into the catarrhal by imperceptible gradations.

TREATMENT—In the space available for the purpose in these pages, the treatment of contagious conjunctivitis cannot be described in detail. It mainly rests upon the action of local astringents, graduated in strength according to the severity and the stage of the disease. In the worst cases the eyelids must be everted, and the

whole of the palpebral conjunctiva carefully touched with a stick composed of one part of nitrate of silver fused with four parts of nitrate of potash. The caustic should be neutralised by a drop or two of a solution of common salt applied by means of a camel's-hair pencil, before the lid is suffered to return into contact with the cornea, and the cauterization must be done carefully and with a light hand, so that the resulting eschar may include only the epithelium; for if the basement membrane is destroyed, there will be danger of subsequent adhesions between the eyelids and eyeball. The cauterization should be repeated about every eight hours, or as soon as the eschar falls, and in the intervals, if the patient is awake, the conjunctiva should be gently syringed every hour with a weak alum lotion at a comfortable temperature. The tension of chemosis may be diminished by radial incisions, outwards from the corneal margin, carried nearly down to the sclerotic; the strength must be supported by good diet and tonics, and the nervous system calmed by analgesics. In milder cases the principle of treatment must be the same, but the local applications less severe, and in chronic cases the local applications must be continued, after apparent recovery, so long as any residual thickening, capable of undergoing eventual contraction, can be found lurking in the palpebral folds.

(d) *Diphtheritic Conjunctivitis.* This malady has chiefly been made known to us by the observations of German writers, and very few authentic instances, it any, have been recorded in this country. But it has from time to time prevailed extensively in Berlin, and might at any time make its appearance amongst ourselves.

SYMPTOMS—Diphtheritic conjunctivitis is attended with great heat and pain, and with very hard, brawny swelling of the eyelids; but its most characteristic symptom is the infiltration of the sub-conjunctival tissue by the so-called diphtheritic effusion, which does not form a pellicle upon the surface, but distends and fills the cavities of the avicular tissue. The result is to produce a pale, firm swelling of the conjunctiva, and a great tendency to rapid sloughing of the cornea. The subjects of the malady are mostly feeble and badly-fed children, and the cases are described as being almost hopeless unless early admitted into hospital.

TREATMENT—The indications for treatment are chiefly to support the strength by suitable regimen, to apply ice or bags of freezing mixture to the lids during the hot stage, and to change the cold applications for hot ones as soon as the period of resolution, absorption, or repair can be said to have commenced. In the meantime iron and quinine should generally be administered internally.

2 *Epucleritis.*—An affection which is apparently but not really conjunctival, being situated in the tissue between the conjunctiva and the sclerotic, is that which has received the name of *epucleritis*, and which was formerly described as 'scleroticus with inflammation of the insertion of a rectus muscle.'

SYMPTOMS—It appears as an elevated patch of congestion, gradually passing into the natural level and appearance of the parts, and seated on,

the ocular surface near the corneal margin, most frequently on the temporal side. On close examination, the congestion, with the exception of a few dilated vessels, is seen to be sub-conjunctival, and to be attendant upon a circumscript but not sharply defined swelling or thickening, which is adherent to the sclerotic, and which presents in the interstices between the blood-vessels, an appearance as if it consisted of some new deposit, generally of a yellowish tint, external to that membrane. The swelling is indolent, chronic, and in itself generally painless, although it is sometimes accompanied by severe neuralgia. The subjects are most frequently women, especially such as are anemic or otherwise out of condition. Episcleritis may last for months with little change, and it seems to be harmless as regards the other structures of the eye.

TREATMENT.—The writer has found episcleritis resist all medication except the internal administration of mercury, to which it will often yield in the course of a short time. The best preparation is the perchloride, in doses not exceeding $\frac{1}{10}$ of a grain, which may usually be combined with five or ten minims of the tincture of perchloride of iron. At the same time it is often desirable to sprinkle a little dry calomel over the swelling once in twenty-four hours, but this application is less important than the internal treatment, and should not be continued unless it is soon and distinctly beneficial.

3. *Hemorrhage*.—Effusion of blood beneath the conjunctiva may occur spontaneously, but is generally traceable either to a direct injury or to violent exertion. Thus it may follow slight blows upon the eyeball, as from a twig or switch, or may be produced by a paroxysm of coughing, especially in pertussis; or may occur from the rupture of a vessel during parturition, or upon lifting a heavy weight. It is always unsightly. When traceable to any of the foregoing causes, the hemorrhage is usually a matter of no moment; but when it happens during the night in young people, it should lead to a suspicion of nocturnal epilepsy, which has often been first discovered by its means. Moreover, in advanced life, more especially when occurring without adequate cause, it may point to arterial brittleness, of a kind which may indicate danger of a like hemorrhage within the cranium. On these grounds it is a symptom which always calls for full inquiry into its causes, and which may sometimes afford useful warning of impending danger.

TREATMENT.—Absorption may be promoted by covering the closed lids by a compress moistened with a lotion of spirit and water, or of tincture of arden and water if an appearance of more decided medication is desired.

II. *Diseases of the Cornea*.—Diseases of the cornea, as already indicated, are often secondary to those of the conjunctiva, and may arise in their course as complications.

1. *Ulceration.*

BRUISING AND STRYMON.—To the present group belong all the corneal ulcerations of purulent ophthalmia, whether infantile or of a later period of life; and also the forms of corneal ulcer which are produced by the friction of solids rendered rough by inflammation, or by

the friction of eyelashes which have been turned inwards by distortion of the tarsal cartilages. When ulceration of the cornea occurs in the course of conjunctivitis, it at once invests the latter malady with a highly formidable character. The corneal tissue, once destroyed by ulceration, is not reproduced in its original transparency, but only as a more or less dense and opaque white cicatrix, which is at the same time disfiguring to the appearance and an impediment to vision. If the ulcer should perforate, the iris almost necessarily becomes adherent to the cicatrix; and if the loss of substance is of large superficial extent, the resulting cicatrix is often thin and feeble, so that it is rendered prominent by the pressure within the eye, producing the condition which has been called 'staphyloma,' and gradually elevating and distorting the surrounding portions of clear cornea. The first effect of the healing of a corneal ulcer is generally to flatten the natural curvature of the membrane; but the secondary effect, if the cicatrix becomes prominent, may be to modify this curvature in various ways. Hence it follows, even when a cicatrix of the cornea is surrounded by a still transparent annulus, behind which an artificial pupil may easily be made by the excision of a portion of the iris, that the surgeon cannot predict with any certainty the quality of the vision which will be obtained, unless he is able, before operating, to determine the state of the corneal curvature. This is only possible when the margin of the pupil is so far free that it can be dilated with atropine sufficiently to render the fundus of the eye visible with the ophthalmoscope. When this can be done, any portion of cornea through which a clear view of the retinal vessels can be obtained by the surgeon will also afford clear vision of external objects to the patient, but, if no such place can be discovered, a very cautious opinion should be given with regard to the degree of benefit which may be hoped for from an operation.

TREATMENT.—The extreme importance of the cornea to the visual function renders it necessary that its integrity should be guarded with the greatest possible care. In any case of conjunctivitis, of even moderate severity, the cornea should be watched from day to day, and any appearance of turbidity about its central portion, or of elevation or irregularity of the epithelium at its margin, should lead to a reconsideration of the treatment which is being pursued. The former of these conditions is the ordinary precursor of sloughing ulcer or necrosis, the latter, of the extension to the cornea of an inflammatory process.

The general principles which govern the treatment of sloughing ulcer are, that the eye should be kept under the influence of opium, which has a marked effect in checking the extension of ulceration by arresting the migration of white corpuscles; that any astringents which may be applied to the conjunctiva should be prevented from coming into contact with the cornea; that strength should be supported, pain relieved, and local nutrition stimulated by hot applications. When the ulcer continues to spread, its progress may often be arrested by diminishing the tension of the globe by the evacuation of the aqueous humour; and this may be accomplished either

by repeated paracentesis at the corneal margin, or by Saemisch's method of cutting through the base of the ulcer, and reopening the incision daily until a process of repair is well established, or by the performance of iridectomy. Of these three courses, the last-named is the most generally applicable. It not only produces the immediate effect which is desired, but it has also the incidental advantage of establishing an artificial pupil at the side of the matrix.

The application of eserine is best effected by using a solution of the neutral sulphate, of the strength of four grains to the ounce of distilled water, and a drop of this solution may be placed within the conjunctival sac twice or thrice daily.

The sloughing ulcers of the cornea which arise from causes other than conjunctivitis, as injury, or failure of nutrition, must be treated upon the same principles which have already been laid down. There are, however, inflammatory ulcers which require the use of local applications of a stimulating kind, among which dry calomel and other mercurials hold a prominent place. Such ulcers have usually a lash of vessels running from the corneal margin, and are often obstinately recurrent, whence they are known as 'recurrent vascular ulcers.' They are usually connected with some manifest systemic derangement, and are often attended by photophobia. They leave scars upon the cornea, of a size and opacity proportionate to their extent and depth, and on this account it is desirable, whatever constitutional treatment may be required, to heal the ulcers themselves as speedily as possible, by the aid of local applications. In the early stages of the ulceration, eserine should be used, but afterwards either dry calomel or an ointment containing from ten to thirty grains to the ounce of the precipitated yellow oxide of mercury, which may be thrown down by any alkali from a solution of the perchloride. This ointment was introduced into practice by Dr Egnestecher, of Wiesbaden and is often called by his name. In very obstinate cases Mr Critchett recommends setons in the temporal regions, but the operation of iridectomy will often afford a still more efficacious remedy. Where there is much photophobia, the use of eserine is especially indicated, because, in addition to its action above mentioned, it produces contraction of the pupil, and thus gives comfort by lessening the quantity of light which is admitted into the eye. If the photophobia is very severe or intractable, it is often beneficial to divide the orbicularis muscle freely at the outer canthus, so as to diminish the pressure which is caused by its spasmodic contraction, and which sometimes seems to be a chief cause of the irritability. After such an incision, a cold compress should be applied, and the patient kept in the dark for a few hours, after which there will often be a marked alleviation of this distressing symptom, and a greatly increased general amenability to treatment.

4. *Inflammation. SYNON.: Keratitis.*—Inflammation of the cornea presents three distinct types, the *suppurative*, the *vascular* and the *interstitial*.

(a) *Suppurative keratitis.* Suppurative inflammation or abscess of the cornea seems to be essentially a phlegmon or boil of the corneal tissue, a portion of which dies, and is cast off in the form of a slough.

SYMPTOMS.—The abscess commences as a very tender grey spot in the cornea, surrounded by a zone of turbidity, and accompanied by a good deal ofiliary neuralgia, as well as by a variable degree of lachrymation, conjunctival congestion, and intolerance of light. Under the influence of atropine, hot fomentations, and such constitutional treatment as the state of the patient may demand, the threatened suppuration is sometimes averted, and the turbidity clears away. More commonly pus is formed, and makes its way either externally, leaving an ordinary ulcer; or internally, producing the condition called *hypopyon*, in which there is pus in the anterior chamber. Sometimes it separates the corneal lamina to a considerable extent before perforating them, and is then called *myx*, from a fanciful resemblance to the lunula at the base of a finger-nail.

TREATMENT.—When suppuration is no longer doubtful, the best practice is to evacuate the abscess by a puncture from within, by thrusting a cutting needle into the anterior chamber near the corneal margin, and then cranking its point to penetrate the cavity of the abscess. The mingled pus and aqueous humour will escape as the needle is withdrawn, and its wound of entrance may be reopened once or twice daily by a probe, so as to insure the complete removal of all inflammatory products, until the healing process has made some way. If the abscess has burst internally before the case is seen, atropine should be applied without delay. If the pupil dilates fully, and the quantity of pus in the anterior chamber is but small, the case may be left to the *vis medicatrix nature*, care being taken to enforce rest and to exclude noxious influences. If the quantity of pus is large, it should be let out by paracentesis; and if the atropine reveals adhesions of the iris, iridectomy should at once be performed. An abscess which has burst externally leaves simply an ulcer, generally with a disposition to heal readily, and requiring only such treatment as has already been described.

(b) *Vascular Keratitis.* Vascular inflammation of the cornea is often a very severe and protracted malady, which usually leaves behind permanent opacity and impairment of sight.

SYMPTOMS.—It commences, in typical cases, by the formation of two crescent-shaped patches of vascularity, one at the upper and the other at the lower portion of the cornea. The patches are formed by the development on the corneal surface of innumerable fine blood vessels, so closely packed together that the interstices which separate them are scarcely discernible by the naked eye, and the affected parts present an uniform aspect of vivid redness. The crescents are somewhat elevated above the general corneal surface, and each crescent is bordered, along its concave or advancing edge, by a line of precursory epithelial turbidity. At the same time that the crescents increase in size, the borders of precursory turbidity are pushed before them; until at first these, and afterwards the crescents them-

lids, may meet and coalesce on the horizontal diameter of the cornea, so that its whole surface may become uniformly red. When this stage is reached, vision is almost abolished, but there may still be much intolerance of light. The corneal tissue is softened, and its margin is surrounded by a zone of sclerotic vascularity, which is visible through the congestion of the conjunctiva. As the inflammation subsides the vascular crescents slowly recede from the centre of the cornea towards its circumference, and finally disappear, leaving behind them a dense opacity of an extremely obstinate character. A severe case of vascular keratitis generally affects both eyes, and threatens a long period of actual blindness, followed by a long period of very imperfect vision. The worst examples of the malady are those which have been treated at the outset by astringent or irritating applications, and, even in the slightest forms, the malady is nearly always obstinate and protracted. As long, however, as the march of the vascular crescents, or their precursory turbidity, has not encroached upon the portion of cornea in front of the pupil, so long vision is not seriously jeopardised.

TREATMENT.—The great object of treatment is to arrest the new vascular development at a comparatively early stage, and for this purpose it is necessary to have recourse to esoteric and sedatives locally, and to such constitutional treatment as the general condition may require. A solution of two grains of the neutral sulphate of eserine to an ounce of distilled water should be dropped into the eye twice daily, and the closed lids should be frequently fomented with hot poppy decoction, or with cold solution of extract of opium in water, according as one or the other temperature is the more agreeable to the feelings of the patient. Apart from any special indication, the medicines most generally useful are those which appear to influence local nutrition through the central nervous system, such as the iodide and bromide of potassium, and the sulphate of quinine. Those, if they are likely to exert a beneficial effect, generally do so speedily, and if the malady should be rapidly extending, it is always prudent to reconsider the prescription without much loss of time. In severe cases, especially when the lids are somewhat tumid and there is much photophobia, a leech may often be applied with advantage, usually over the temporal muscle, close to the outer margin of the orbit, or a little blood may be taken more rapidly, by means of Heurteloup's artificial leech, and when, notwithstanding treatment, the malady pursues its course unchecked, a large iridectomy should be made without undue delay. The operation not only tends to arrest the vascular formation, but it also leaves a lateral pupil through which good sight may often be obtained long before the transparency of the central parts of the cornea is restored.

Development of vessels upon the cornea.—It is necessary carefully to distinguish vascular keratitis, properly so called, from that development of vessels upon the cornea which may occur in connection with the cicatrization of ulcers, or in consequence of the friction of lids left granular by conjunctivitis. In both these forms the new vessels are arborescent and irregu-

lar in their distribution, instead of being closely packed together: and they are not attended by the pink zone of circum-corneal congestion, which is never absent in true corneal inflammation.

The vessels which attend the formation of cicatrices generally twindle in course of time, while those produced by granular lids, and when, when they are very abundant and closely set, constitute the condition called *pannus*, will often disappear without direct treatment if the state of the lids themselves can be favourably modified by the application of astringents. In many cases the vascular network of pannus will be comparatively absent from the lower third of the cornea, so that sight may be much improved by an artificial pupil made in a downward direction. When pannus covers the whole cornea with a close vascular network, so that sight is almost destroyed, and when it resists milder treatment, it may sometimes be cured by inoculation with the discharge of infantile purulent ophthalmia. The pus is inserted between the lids, and the artificial malady suffered to run its course unchecked, except by cleanliness and frequent bathing. When the discharge has ceased, the cornea will often clear in a surprising manner, and its abnormally vascular state protects it, to a very great degree, against the risk of sloughing. Still, this risk is by no means absent, and the treatment by inoculation should be regarded only as a last resource.

(c) **Interstitial Keratitis.** This is a chronic malady which is seen chiefly or perhaps exclusively, in the subjects of inherited syphilis, who possess the peculiar teeth and *facies* which Mr. Hutchinson has shown to be characteristic of their inheritance. The disease was long described as a variety of 'serumous ophthalmia,' and, although the late Sir William Wilde pointed out how frequently it was associated with deafness, and also laid stress upon the value of perchloride of mercury in its treatment, its syphilitic character seems to have been first suspected by Mr. Hutchinson who having once obtained the clue, followed it with characteristic diligence until he arrived at a conclusive demonstration of the accuracy of his suspicion.

SYMPTOMS.—Interstitial keratitis commences as a slight cloudiness of the central portion of the cornea, with some roughening or irregularity of the epithelium. It extends from the centre towards the margin, and is liable to be attended, in different cases and at different stages of its course, by variable degrees ofiliary and corneal congestion, and intolerance of light. If neglected, or if treated by irritants, it is liable to assume the characters of vascular keratitis, and also to extend to the iris, in such instances often doing irreparable mischief. It is most common during childhood, but its appearance may be delayed until adolescence, or even until adult age. It attacks both eyes, one commonly somewhat later than the other, and its course is often protracted over several months. When severe, it leaves some residual cloudiness of the cornea, and, even when mild, it is doubtful whether the cornea ever entirely regains the transparency of health. Still, when a case is seen and judiciously treated early, the prognosis may generally be a favourable one.

TREATMENT.—The treatment consists primarily in the avoidance of all irritants, the use of eserine and local sedatives; and the administration of perchloride of mercury, or of iodide of potassium, with or without iron or cod-liver oil. When they are not contra-indicated by any special circumstances, the perchloride of mercury and the oil are the remedies on which the greatest reliance may be placed. The earliest indications of photophobia, showing, as they do, that light is acting as an irritant, should be met by confinement to an almost darkened room, and by frequent bathing of the closed lids with cold water, but in fine weather daily exercise should be taken in the open air, the eyes being covered for the time with a black silk bandage and compresses of carbol wool, so as to exclude light entirely. As soon as photophobia subsides, these precautions may be left aside—the eserine and mercury being still continued, at least until the acute stage of the malady has entirely passed away. After this the absorption of residual opacity may be promoted by the application, once daily, of a normal of an ointment containing a small quantity (about ten grains to an ounce) of the precipitated yellow oxide of mercury.

In cases which have been neglected, or aggravated by irritants in their early stages, and in which the phenomena of ordinary vascular keratitis become grafted upon the interstitial, it is generally desirable to perform iridectomy with as little delay as possible.

3. *Arvus Senilis*.—The condition thus named (although the adjective is not always appropriate) is fully described elsewhere (See *ARVUS SENILIS*). It may be distinguished from the peripheral zones of opacity, which are sometimes left after the subsidence of certain forms of keratitis, by the circumstance that arvus never extends quite to the margin of the cornea, but is always surrounded by an annulus of transparent tissue.

Besides the foregoing, there are a few other forms of corneal disease, of comparatively rare occurrence, which it would be beyond the limits of these pages to describe, but which must be treated on the same general principles; and there is also the malformation known as 'conical cornea,' which falls wholly within the domain of surgery.

III. *Diseases of the Sclerotic*.—Diseases of the sclerotic, which were once regarded as a numerous and important group, have been reduced by recent investigations to comparatively insignificant proportions.

Inflammation.—*Synov.*—*Scleritis*.—Excepting in a narrow annulus immediately around the cornea, the sclerotic is almost extra-vacular, and any real inflammation of its structure is almost confined to this particular region, where it seldom occurs excepting as a complication, or as a part of some of the more severe forms of iritis or keratitis, especially when either of these affections extends to the ciliary body. In such cases we often see the sclerotic undergo inflammatory softening, as a result of which the ciliary region may be much altered in shape, leading to the distension of the eyeball and to the traction of the recti muscles, and becoming distinctly elongated. Occasionally the sclerotic may be so

much softened and thinned as to bulge into irregular prominences around the cornea, generally under the upper lid; and this condition is described as *sclerotic staphyloma*.

TREATMENT.—The inflammations thus arising call for no other treatment than that which is demanded by the more important inflammations of the cornea, the iris, or the ciliary body, with which they are associated; except that any evidence of yielding of the sclerotic would be a reason in itself for the performance of iridectomy, in order to preserve the shape of the eyeball by diminishing its tension. It was once believed that the sclerotic, in its character of a fibrous membrane, was especially prone to gouty or rheumatic inflammation; and it is perhaps true, though certainly not proven, that the tendency of iritis or of keratitis to spread to the anterior sclerotic zone is more marked in persons of gouty or rheumatic diathesis than in others. The possibility is at any rate sufficient to require, in all these cases, an investigation of the tendency to lithic acid formation, and the use of appropriate remedies when this tendency is discovered. But a large proportion of the examples of supposed gouty or rheumatic ophthalmia are nothing more than cases of the subacute or remittent form of glaucoma, and the pain associated with them is not really rheumatic but simply tensile. Vision has been irretrievably lost, in hundreds of instances, because a belief in the rheumatic character of these affections has interfered with the timely performance of iridectomy, and the proposal to adopt the epithet 'rheumatic' in any form of ophthalmia, is one which should be scrutinised very closely before it is accepted as a guide to practice.

IV. *Diseases of the Iris*.—In so far as they come into the province of the physician, diseases of the iris are not numerous and are almost limited to the varieties of inflammation of that membrane.

1. *Inflammation.* *Synov.* *Iritis*.—Iritis may be classified according to its actual or supposed causes, as rheumatic or syphilitic; or according to the nature of the morbid process, as *plastic*, *serous*, or *suppurative*. The former classification must often rest upon very slender grounds, and the latter has the great advantage of expressing facts rather than inferences.

(a) *Plastic Iritis.* *Symptoms*.—In plastic iritis the first symptom is usually some loss of the natural lustre of the surface of the iris, and of the clear definition of its fibres, together with some dimming or alteration of its colour. These changes are probably always due to turbidity of the aqueous humour, and they may be imitated more or less closely by turbidity of the cornea, and especially by disturbance of its epithelium. In iritis, however, they are associated with a diminished range and quickness of pupillary variation under variations of light, and, in a short time, with the effusion of plastic lymph, by which the margins of the pupil become tied down, here and there, to the surface of the anterior capsule of the crystalline lens. At the same time there is usually some congestion of the conjunctiva, and of the area of the vessels immediately around the cornea in the sclerotic. There is frequently more or less

pain, especially towards night, but this is a very uncertain symptom. In severe cases, and especially in such as are clearly syphilitic in their character, the quantity of effused lymph may be very considerable, so as quite to cover the pupil, while in mild cases it is only sufficient to *fasten down* the margin here and there. Iritis is sometimes a very insidious and seemingly slight affection, the real gravity and importance of which may be wholly overlooked by the patient.

TREATMENT.—The first principle of treatment is to prevent the formation of adhesions, or to break them if they have been formed; and for this purpose our main reliance must be placed upon the instillation of atropine. The anatomical structure of the eye is such that a moderately contracted pupil is in contact with the lens-surface, while a fully dilated pupil is separated from it by a film of aqueous humour. Hence, as long as the pupil is contracted, any lymph which is effused tends to the immediate formation of adhesions; while, as soon as the pupil is dilated, the lymph diffuses itself harmlessly in the surrounding fluid, and no adhesions are produced. In ordinary circumstances, and in cases of only ordinary severity, the iritis then runs its course without inflicting any permanent injury, and vision is completely restored as soon as resolution has taken place. When, on the contrary, the pupil cannot be dilated, the lymph deposited in the area of the pupil forms an impediment to vision; and the adhesions themselves tend to render the iritis a recurrent affection, which is apt to return again and again until the eye is disorganised and destroyed.

The first principle of treatment is, therefore, to produce and maintain dilatation of the pupil, and for this purpose it is necessary to use a watery solution of a salt of atropine. The neutral sulphate is the one best adapted for the purpose, and it should generally be of the strength of four grains to the ounce of distilled water. The pharmacopœial solution of atropia, which contains spirit, should be avoided on account of its irritating action. Of the pure watery solution, a drop should be carefully placed within the lids by a dropping-tube or quill, repeated in five minutes, and again in another five minutes, and this threefold application should be repeated three times a day. A mydriatic agent still more powerful and more rapid in its action than atropine has lately been introduced into practice in *dehousin*, the active principle of an Australian shrub, *Duboisia myoporoides*. *Duboisin* should be used in a watery solution, of the strength of four grains to the ounce; and it is said to have less tendency than atropine to produce local irritation. If the pupil can be fully dilated in twenty-four hours, no other treatment will be necessary than to maintain the dilatation by using atropine less frequently, and to protect the eye from being injured by exertion, or by exposure to great variations of temperature or of light. If, on the contrary, after the use of atropine for twenty-four hours, the pupil either remains contracted or dilates irregularly, showing that it is bound down here and there, it is necessary to have recourse to mercury without further delay, and

to use one of the preparations, such as blue pill or calomel, with which the effect of the medicine upon the system can be rapidly secured. There is never any occasion to carry the effect of the mercury farther than to the formation of a slight line upon the gums; and, in most cases, as soon as this line is perceptible a notable amelioration of the eye-symptoms will be observed. It is desirable, however, that this degree of mercurial influence should be reached quickly, in order to cut short the disease as soon as possible; and when it has been reached, it will usually require to be maintained, for some days at least, by the administration of smaller and less frequent doses. In favourable cases, under the combined influence of atropine and mercury, the effused lymph will be absorbed, the adhesions broken through, and the eye restored to its original condition. In those of a less favourable character the inflammation will, indeed, subside, but the adhesions will remain, and the pupil will be left permanently more or less crippled and distorted. Whether or not sight will be impaired will chiefly depend upon whether the effused lymph has formed a film or membrane across the pupillary opening. In the worst cases, notwithstanding treatment, the inflammation may extend to the ciliary body and choroid, and may produce functional destruction of the eye. This scarcely happens except when the iritis has been of great original severity, and when it has been neglected, or aggravated by irritants in its early stages. Even the suspicion of iritis should absolutely preclude the use of the astringent applications on which we have mainly to rely in the treatment of the inflammations of the conjunctiva.

If an iritis is not seen until it has been three or four days in existence, so that the adhesions have had time to acquire a certain degree of firmness, it is not desirable to wait twenty-four hours before having recourse to mercury. The mineral should be given without further delay, so that it may be abandoned if atropine should dilate the pupil, and may be pushed if dilatation cannot be produced.

While the atropine, or atropine and mercury, are being employed, the remainder of the treatment must be governed by general considerations. Rest of the other eye must be strictly enforced, local depletion may be practised whenever the congestion is considerable in degree; and such a regimen and mode of life must be prescribed as the patient can bear. Unless there is photophobia, it is seldom or never necessary to exclude light altogether from the eye, and, when photophobia is present, it is better to apply a protective bandage than to keep the patient in a dark room. The latter practically excludes him from cheerful companionship, and leaves him to dwell upon his troubles in darkness and solitude. Pain, if present should always be subduel, either by combining a sufficient dose of opium with the mercury, or by the subcutaneous injection of a solution of morphia. However the anodyne is administered, provision should be made for repeating it sufficiently often to produce and maintain the desired effect.

When recovery takes place leaving adhesions, these will, in the majority of cases, lead to a second attack of iritis, and this is almost always

the predecessor of regular recurrence. In a few cases, however, the second attack does not follow; but, whenever it occurs, the tendency to future mischief should be stopped by surgical means, either by the detachment of the adhesions or by the performance of iridectomy.

(4) *Serous Iritis*.—The serous form of iritis differs from the plastic in the greater quantity and the more liquid condition of the effusion, which does not form a lichenous, but distends the eyeball and compresses its contained structures. In a well-marked case the pupil is contracted and impossible to atropine (which in all probability is not absorbed), the aqueous humour is turbid, the iris is pushed back and its anterior surface appears concave, vision is greatly impaired, and the eyeball is perceptibly hardened to the touch.

TREATMENT.—Until the distension is relieved, no remedies will be effectual, and, when it is relieved, they generally cease to be needed. The treatment should be either by frequently repeated paracentesis of the anterior chamber or by a large iridectomy, and the latter is generally to be preferred. Serous iritis occurs chiefly in persons of unhealthy or broken-down constitution, which may perhaps account for the unorganizable character of its products. As soon as the distension of the eyeball is relieved, the pupil is readily dilated, and the iritis soon subsides.

(c) *Suppurative Iritis*.—In a small number of cases iritis assumes from the first a suppurative character, and leads to the formation of pus in the anterior chamber.

TREATMENT.—Such a condition calls for atropine; for stimulating and tonic medicines rather than for mercury, and for the evacuation of the pus by paracentesis if it is considerable in quantity, or if its presence appears to be a source of increased irritation.

2. *Inflammation of the ciliary body and choroid.*

SYMPT. *Cyclitis, Irido-choroiditis*.—In some instances, which fortunately are not numerous, iritis is not confined to the membrane in which it originates, but spreads backwards to the ciliary body and the choroid. The most marked examples are those in which the original inflammation has been excited by morbid changes, resulting sometimes from disease, but more frequently from injury, in the opposite eye, and these cases are called *sympathetic ophthalmia*. They have been abundantly shown to depend upon the propagation of peripheral irritation through a nervous centre, and they point very clearly to the presence of some central nerve-irritation, or functional failure, as the essential point of difference between the iritis which dies out as a localized affection, and that which spreads by continuity to the deeper parts of the eye. However occasioned, the issue of declared irido-cyclitis or irido-choroiditis is generally disastrous; for the inflammation is always of a plastic character, and the effused lymph is scarcely ever absorbed in time, or with sufficient completeness, to prevent its contraction from inflicting profound injury upon the visual apparatus. The perceptive layer of the retina is not only in contact with the choroid, but the rods and cones derive the materials of their nutrition from the chorio-capillaris; and hence, as regards these delicate structures, an inflamma-

tion of the choroid, upon which they are directly dependent, is of far greater importance than an inflammation of the retina itself, which may be limited to the connective tissue of the fibre-layer, and may leave the perceptive elements almost unaffected.

SYMPTOMS.—The first sign of the extension backwards of iritis is usually furnished by tenderness of the ciliary zone, so that this region feels acutely the slightest touch of a probe, or of the end of a rolled paper spill, which is a more delicate instrument for testing the sensibility of the ocular surface. At the same time there is always a greater degree of impairment of vision than the iritis alone will explain, together with increased general congestion of the eye, and, in many cases, with an appearance of visible vessels on the iris.

TREATMENT.—The treatment to be pursued does not differ materially from that which is required by the more severe forms of simple iritis, and consists of depletion from the temple, generally by means of Leuvenhoup's leech; the application of atropine; the administration of mercury, both internally and by inunction upon the brow; the control of pain; and the maintenance of strength. In sympathetic cases, the eye in which the mischief originated should be removed, even although the usefulness of this proceeding is somewhat doubtful when once the secondary affection is established. It is often necessary carefully to continue the use of mercury for a long period, generally in the form of small doses of the perchloride combined with iron, and it is chiefly when this has been done that some small vestige of vision is saved out of the wreck. The lens, in such cases, often becomes coated by lymph, and ultimately requires removal, and it may be necessary to perform iridectomy for closure of the pupil more than once, in consequence of the tendency of the artificial opening to be drawn together again by contraction. On account of the severity of sympathetic ophthalmia, and of its generally unfavourable termination, it is a rule of practice to anticipate its occurrence, and to remove a diseased or injured eye which is likely to produce it before the mischief has been done.

V. *Diseases of the Crystalline Lens* are separately treated of under the article CATARACT.

VI. *Glaucoma*.—In its modern signification, this word is applied to denote all the conditions which are produced by a morbid increase of tension within the eye, that is to say, by an excess of its contained fluids, and the different forms of the affection are mainly due to differences in the rate at which the tension increases.

SYMPTOMS.—If the increase be rapid, the loss of sight will be rapidly produced, and will be associated with other changes occasioned by sudden interference with the circulation and innervation, and by sudden stretching of the ocular tissues. When, on the other hand, the increase of tension is very gradual, so that the eye has time to become accustomed to the new conditions as they are produced, the symptoms often present a deceptive resemblance to simple atrophy; and these cases were at one time described as 'atrophy with excavation of the optic nerve.' In some of the more acute forms of increased tension, the

pupil presents a clouded aspect of a greenish colour; and it was to cases of this class that the word *glaucoma* (from *γλαυκός*, sea-green) was originally applied, at a time when the pathology of the condition was not understood. When this pathology was rendered clear, and when it became known that the *glaucoma* of the ancients was in all essential respects identical with cases in which the most manifest symptoms were of a different kind, the word was retained as a convenient general term, to express states of disease to which it had no longer any apparent reference, and hence we still speak of *glaucoma*, although, in the great majority of the cases in which we do so, the green aspect of the pupil is conspicuous by its absence.

The estimation of increased tension by the fingers is a matter which requires the *tactus eruditus*, and is best accomplished by directing the patient to close the eyes gently, and to cast them downwards. The tips of the two fore-fingers should then be placed upon the upper lid immediately below the margin of the orbit, and, when one finger has fixed the eye by holding it gently back against the orbital contents as far as it will recede, the other estimates the degree in which it may be dimpled by slight pressure. This degree varies to some extent in different persons within physiological limits, but a morbid increase of tension can scarcely be missed if it is looked for. Moreover, the diagnosis of *glaucoma* does not rest upon increased tension alone, but upon the combination of increased tension with decreasing sight. The rate of slow increase which may simulate atrophy, or of rapid increase which may simulate inflammation, are matters of detail which should not, in either case, be suffered to obscure the true nature of the morbid process.

TREATMENT.—The treatment of *glaucoma* is entirely surgical, the affection being capable of arrest by iridectomy or sclerotomy in the great majority of cases. In the more acute forms, an operation, if performed sufficiently early, usually restores vision to its integrity, but the time during which this can be done is limited, and in the more chronic forms no operation will do more than preserve what amount of sight is still retained. Hence it is important that treatment should not be delayed by any error of diagnosis, and the points to which attention should chiefly be directed, in any case of impairment of vision in which the question may arise, are increasing hardness of the eyeball as determined by palpation, and gradual contraction of the field of vision. Whenever the eye is becoming harder, and the circumferential extent of vision is narrowing, the case is one in which an operation should be accomplished with as little delay as possible. At the same time, until the operation can be performed, a four-grain solution of eserine should be applied every four hours, this drug having a marked effect in controlling and diminishing tension. The more acute cases of *glaucoma* are attended by much pain from the distension of the ocular tunics, and often by congestion and inflammation, the results of this distension; and such cases were at one time described as ‘acute internal arthritis ophthalmica,’ or by some similar name. Vision has

been irretrievably lost, in hundreds of cases, by endeavouring to control this form of *glaucoma* by medical treatment, to the neglect of operation; and the erroneous practice has been kept alive by the circumstance that some of the cases will undergo partial and temporary amendment. In such circumstances, however, the vision never rises to the degree of acuteness which existed prior to the attack, and the amendment is never more than temporary. Another increase of tension soon occurs, and, without surgical aid, blindness sooner or later closes the scene.

VII Diseases of the Optic Nerve and Retina.—As shown by the ophthalmoscope, these diseases cover a very wide field of pathology. In order to understand them accurately, it is necessary to bear in mind the anatomy and relative arrangement of the affected tissues. The optic nerve in the orbit is invested by a double sheath, and the interval between its layers, which is continuous with the sub-arachnoid space, terminates in a cul-de-sac towards the eyeball, the two layers becoming intimately united where they blend with the sclerotic. At this point, the opening in the sclerotic for the admission of the optic nerve is crossed by a film of perforated connective tissue, the *lamina cribrosa*, with which the sheaths of the nerve-fibres blend, or in which they are lost, so that the nerve anterior to the lamina consists of a bundle of unsheathed fibres, enveloping the central artery of the retina, which enters the eye with them, and the central vein of the retina, which passes out in the same position. On entering the eye the nerve-fibres bend round to form the anterior layer of the retina, which contains also the retinal blood-vessels almost to their ultimate divisions, together with some delicate connective tissue. The capillary circulation of the nerve itself is derived from the anterior cerebral artery, and is distinct, save for a very slight amount of anastomosis, from the capillary circulation of the sheath, which is fed by the arteries of the pia mater. It follows that hyperæmia of the sheath, or of the circle surrounding the nerve, may exist without hyperæmia of the proper nerve-tissue, and it has been supposed that fluid pressure in the intertunical space may interpose an obstacle to the circulation in the vessels which pass through the sclerotic foramen, and may thus occasion drooping of the termination of the nerve within the eye. Of the two foregoing conditions, either may undergo resolution harmlessly, or may produce such changes in or around the nerve as to occasion atrophy and loss of sight. Neither of them interferes with sight directly, because the circulation may be seriously disturbed by a degree of pressure which is insufficient to stop the conduction of impressions through the nerve-fibres. There is yet a third condition, properly called optic neuritis, or *neuritis decussatoria*, in which the capillary network of the nerve itself participates in changes propagated downwards from the cerebrum, and in which impairment of vision holds a very early place among the symptoms.

1. *Perineuritis.*—The true perineuritis, in which the unchanged nerve-disc is surrounded by a cone of high vascularity, is only seen as a

result of meningitis, which may be either tubercular or due to other causes. It was at one time hoped by Bouchut, by whom this especial phenomenon was first described, that perineuritis might serve as a diagnostic sign in cases of doubtful meningeal inflammation; but this expectation has not been realised. The perineuritis itself has only been observed in cases the character of which was scarcely doubtful, and which, in most instances, have terminated fatally. Very probably, however, it would be found, if looked for, in those cases of exanthematous and other fevers which are attended by cerebral symptoms, followed after recovery by impairment of vision. In these we eventually find, as a rule, a partial nerve-atrophy, which does not lead on to complete blindness, but which does not appear to be susceptible of improvement, and this partial atrophy may no doubt be due to the pressure of perineurial exudation during its contracting stage.

TREATMENT. The treatment of perineuritis must generally be that of the affection in which it has its origin, but, in any case in which this symptom had been detected, it would be a question whether mercury should not be cautiously administered for a considerable time after convalescence, in order to promote the absorption of any effused lymph by which the optic nerve entrance might be constricted.

2. *Choked Disc Syndr.* : *Drainage of the Optic Nerve Entrance.* This condition chiefly arises in connection with intracranial tumours, whether syphilitic, tubercular, or of some other kind, and it almost invariably affects both eyes. It was formerly supposed to be due to the pressure of fluid driven down the intercranial space around the nerve, and so constricting the latter at the terminal *cul-de-sac* as to impede the outflow of venous blood. This hypothesis is now generally abandoned, but the condition visible with the ophthalmoscope is one of distension and tortuosity of the retinal veins, arrest of the capillary circulation, impediment to the arterial inflow, dropical effusion into the disc-tissues, and, sometimes, secondary inflammatory changes, such as effusion and cell-proliferation, comparable to the erythema which occurs in the integument of a dropical limb. All these changes may exist without impairment of vision, because they neither affect the perceptive layer of the retina, nor arrest the conduction through the nerve-fibres. At a later period, however, when any plastic elements in the exudation begin to undergo contraction, the interference with the circulation becomes more complete, the nerve-fibres themselves become compressed, and then failure of sight commonly occurs. At the same period, the nerve passes into a state of atrophy from the interference with its circulation, and these cases of nerve-atrophy were our sources of great perplexity to surgeons, and were referred to alcohol, tobacco, and to other causes which probably had very little to do with them. In consequence of the sight not being affected during the preliminary stage, the occurrence of this stage was for a long time absolutely overlooked, and was only discovered when physicians began to use the ophthalmoscope, as an ordinary instrument of diagnosis, in all cases of cerebral affection. It was then soon established,

notably by the labours of Drs. Huxtable, Jackson, Buzzard, and Clifford-Allbutt, that the atrophy had been preceded by swelling of the disc and by obstruction of its circulation; and it was shown before long that the cases of atrophy which had this history were recognisable, after the swelling had passed away, by the tortuosity of the retinal veins which was left behind, and by the way in which these veins were lifted into bold curves at the margin of the disc; this alteration of their original course having been due to the swelling, and remaining after the swelling had subsided. The contraction of the effusion, and the consequent atrophy of the nerve-fibres and closure of the capillary vessels, would be likely to occur earlier in some parts of the disc than in others; and hence, at the time when commencing failure of sight first induced the patient to seek advice on account of it, the disc was commonly seen to be invaded by sectors of whiteness, but to retain its vascularity, or perhaps more than its normal vascularity, in other parts, while, at the same time, the sight was first lost in those regions of the retina the fibres from which were first compressed. Hence it follows that a partial invasion of the disc by atrophic changes, and a partial invasion of the field of vision by blind portions are among the earliest symptoms in cases of the class under consideration; and these symptoms were at one time referred rather to the nervous centres than to the retina or the disc itself, to changes in which they are now attributed. A not uncommon clinical history in such cases is that there has been constitutional syphilis, imperfectly treated, and ultimately producing headache or other cerebral symptoms, which have probably called for the administration of iodide of potassium and have been relieved by it. Some weeks afterwards there is for the first time a complaint of failing sight, and then the ophthalmoscope reveals that the discs are passing into atrophy, that the retinal veins are lifted into prominent curves at the disc-margins, and that their further course over the retina is generally serpentine. In many cases, the recovery of the patient, as far as general health is concerned, leaves the precise character of the intra-cranial mischief doubtful, but, in fatal cases, a tumour is the morbid condition most frequently discovered. *See OPTHALMOSCOPE IN MEDICINE.*

When the merely passive dropical effusion into the disc becomes complicated with inflammatory changes, as results of the disturbance of the tissues, the sight begins to fail before atrophic changes become manifest, and such cases are very difficult to distinguish from those in which there is (3) *primary or descending neuritis*. The blood-supply of the optic nerve being derived from the anterior cerebral artery, we may reasonably expect to find capillary engorgement of the nerve-substance of the disc in connection with arterial hyperæmia of the brain; and this capillary engorgement may pass into inflammation, either of local origin or by transmission downwards from above. In any case, if the first changes in the disc are of the character of neuritis rather than of obstruction, we see capillary or arterial hyperæmia of the nerve-substance rather than venous congestion; and effusion of plastic material upon the disc itself, with comparatively little prominence.

or disc-swelling, and with comparatively little extension over the disc-margins upon the surrounding retina. At the same time, even in the early stage of the affection, we find great impairment of sight, the conducting power of the nerve-fibres being seriously injured. Such cases are frequently syphilitic, and, unless the absorption of the effusion should be quickly brought about by treatment, its contraction, like that of the effusion of obstruction, soon occasions atrophic changes. In these cases, however, the swelling having been absent or inconsiderable, the vessels do not show that elevation into bold curves at the disc-margin which has already been described; and the contraction being interstitial in the nerve-substance, and from the first affecting veins and arteries in an equal degree, the arterial inflow is diminished *pari passu* with the diminution of the vein-channels, and the latter vessels are seldom distended in such a manner as to render them distinctly varicose or tortuous. The ultimate result is a white disc, on which the arteries and veins are dwindled to threads, or at least greatly reduced from their normal calibre.

We may therefore have three conditions which in their typical forms are tolerably distinct, but which are prone to run into one another by almost imperceptible gradations, and which may all lead on to atrophy and complete blindness—namely, perineuritis, neuritis, and choked disc. The liability to the last-mentioned condition should be carefully remembered by physicians, and should lead to careful ophthalmoscopic examination in all cases of obstinate headache or other cerebral symptoms of obscure origin, more especially in a patient with a syphilitic history.

TREATMENT.—It is manifest that the best hope of preventing ultimate blindness, in persons in whom choked disc has occurred, will be secured by the administration of medicines calculated to assist the absorption of the effusion, and by continuing these medicines with comparatively small reference to the general symptoms, until the discs have cleared. The writer has seen such clearing occur, without loss of sight, in circumstances which rendered it almost certain that neglect of the disc-effusions would have been followed by blindness at no distant date. The same general rule will apply, of course, to the more directly inflammatory effusions of neuritis or perineuritis; and, when we find any one of the three conditions passing into atrophy, or when we find commencing atrophy in discs which show traces of past effusion, the principle of treatment is to endeavour to promote the absorption of any contracting material which may be the physical cause of the atrophy; and then, when this has been done, to seek to stimulate the nutrition of the nerve-fibres, and to assist them to recover from the shock which they have sustained. The mode of fulfilment of the first indication must depend mainly upon whether there is a history of syphilis, and, if so, upon the manner in which it has been treated. In the numerous cases in which a short course of mercury has been administered, enough to alleviate secondary symptoms, but wholly insufficient to eradicate the disease, it will generally be desirable to give iodide of potassium in full doses for a time, and to follow this by the prolonged ad-

ministration of the perchloride of mercury, in the hope of really curing the patient. There are, in the writer's opinion, few things better worth remembering in therapeutics than that the iodide is immeasurably the most valuable drug which we possess as a remedy for a late syphilitic symptom, is none the less almost useless as a remedy for constitutional syphilis. It will remove the present symptom, speedily and often completely, but it can scarcely be said to have any tendency to prevent the recurrence of syphilitic symptoms at a future time, in the same or in some different form. For this purpose, the only trustworthy agent is mercury, and therefore, while the administration of the iodide for a sufficient time, and in sufficient quantities to test its power of doing good, will be enough in the cases in which syphilis is neither known nor suspected, the iodide must be followed by mercury whenever a syphilitic history of the affection is either clear or highly probable. The second indication, to stimulate the nutrition of the nerve-fibres, is usually best accomplished by strychnia, given at such intervals and in such doses as to produce evidence of its constitutional effect before its administration is abandoned. It may perhaps be most effectually given by hypodermic injection, but this is a point which must be settled in accordance with the circumstances of the case in each individual instance.

3 *Sclerosis of the Optic Nerve.*—Besides the consecutive forms of atrophy above enumerated, there is yet another of common occurrence, which is either a primary sclerosis of the optic nerve, or a sclerosis secondary to a similar affection of other parts of the nervous centres. This form of atrophy is not preceded by effusion, nor is it attended by any marked decrease in the calibre of the central vessels of the retina, even when the capillary circulation of the disc has almost wholly disappeared. It is often seen in connection with disease of the spinal cord, as in locomotor ataxia, and also occurs in apparently healthy people, seemingly as a purely local affection.

Sclerosis is easily distinguished from the atrophy consecutive to effusion, whether active or passive, by the circumstance that the effusion, as it undergoes contraction, tends to render the nerve-tissues opaque as well as to bleach them, and thus leaves a disc-surface of an almost ivory whiteness and of uniform colour. In sclerosis, on the other hand, the nerve-tissue disappears to a great extent and reveals the mottled surface, often of a bluish-white tint, of the lamina cribrosa. When this is plainly seen, and when, at the same time, the vessels are neither much diminished in calibre nor altered in their normal curvatures, sclerosis may be assumed to exist; and this form of atrophy may also be distinguished from that which is produced by the most chronic forms of glaucoma, by the circumstance that in the latter the vessels bend into the excavated disc at its margin, while in the former they pass over the margin in straight lines or nearly so. Chronic glaucoma would also be distinguished by the character of the failure of sight, which would be marked by regular or almost concentric contraction of the field of vision, even when central vision was only a little

impaired; and also by the gradual hardening of the eyeball, which would be present in glaucoma and absent in nerve-sclerosis. Still it cannot be denied that this particular diagnosis is not without its difficulties, and that in certain cases it has given rise to differences of opinion between men of large experience on all sides of the question at issue.

The diagnosis is important as well as difficult; since the mischief of glaucoma may admit of arrest by iridectomy or sclerotomy, so that to mistake chronic glaucoma for atrophy, and to neglect operation, may be to condemn the patient to unnecessary blindness. The opposite error can at least do no harm, and therefore, whenever a doubt really exists upon the point, the most proper course is to give the benefit of that doubt to the patient, and to advise the performance of an operation which cannot injure and which may relieve him. The atrophy of sclerosis scarcely admits of treatment, but it may perhaps sometimes be delayed, or even prevented from becoming complete, by the administration of full doses of strychnia and iron.

4 *Atrophy from other causes*.—Besides the foregoing forms of atrophy, there is a variety which appears to be associated with chronic lead-poisoning, and in which the discs may acquire a peculiar gray or bluish tint; and the optic nerves may also undergo secondary wasting in consequence of other conditions presently to be mentioned, such as obstruction of the central artery by an embolus, or the long continuance of pigimentary retinitis.

5 *Retinal Hemorrhage*.—The chief disorders of the retinal circulation displayed by the ophthalmoscope are hemorrhages, which may be attended by very different circumstances, and may present widely different characters.

a. *Single*.—When blood proceeds from one of the larger veins of the retina, which yield a considerable quantity, and which are situated immediately underneath the limiting membrane, the hemorrhage usually spreads out over the fundus as a red patch of uniform colour and aspect, and vision is suddenly, and sometimes almost totally, obscured. The writer has seen such bleeding occur from the yielding of a vessel during parturition; but this accident is extremely rare, and the large hemorrhages in question are certainly more common in women at the period of cessation of the menstrual function than under any other circumstances. At this time, and when the health is not seriously affected, a favourable prognosis may be given with some confidence, for the blood will before long be absorbed, and restoration of vision, at least to a considerable degree, may be expected. The writer has once seen complete restoration to the normal standard, but this is an exceptional occurrence.

Treatment.—The only treatment necessary is to pay attention to the requirements of the general health; and to prescribe such diet, medicines, regimen, and habits as may tend to calm and equalise the circulation, and to prevent local congestions. The occurrence of sudden loss of sight in one eye will justify the suspicion of hemorrhage, but the suspicion can only be converted into certainty by the ophthalmoscope.

6. *Multiple*.—A form of venous hemorrhage

which at first seems less formidable, because it is attended by a smaller degree of immediate interference with sight, but which calls for a less favourable prognosis, is that in which the hemorrhages are multiple, often singly of small size, and scattered over the whole fundus of the eye. The appearances which they present differ, apparently in accordance with their precise position in the retina. If they proceed from vessels which are superficial, the blood is spread out, as in the last variety, in round or oval patches beneath the limiting membrane, but, if the vessels lie a little deeper, and are fairly engaged in the fibre-layer, the blood will separate the fibres and find its way between them forming flame-shaped or brush-like patches, which are often very numerous. Such multiple hemorrhages are very slowly absorbed, and have a tendency to recur, so that they must always be regarded as placing the sight in serious jeopardy. They are often monocular, and they do not point to any definite disturbance of the general health. The only endeavour so to connect them with which the writer is acquainted was made by Mr Hutchinson, who described some cases of flame-shaped hemorrhages in persons all of whom he said were 'gouty,' but it will certainly be the experience of most practitioners that flame-shaped hemorrhages occur in many patients who are not 'gouty' in the ordinary sense, and that they do not occur in vast numbers of those about the reality of whose gout there can be no question. The presence of multiple hemorrhages is sometimes attended by a considerable degree of irritation, or even inflammation, in the tissues among which the blood has been effused, and this condition, in which the retina between the blood-spots may become opalescent or turbid, has been described as a form of retinitis—*Retinitis apoplectica*. The element of inflammation, in such instances, is probably merely a reaction consequent upon the injury inflicted upon the tissues, and it cannot be inferred that the bleeding is itself the result of any inflammatory process.

Treatment.—In this, as in the former variety, there is no special indication for treatment, which must be confined to the correction of any manifest disorder of the general health, followed, in most instances, by the administration of iodides or bromides, as medicines calculated to assist in the absorption and removal of the effused products. Any indication of a general hæmorrhagic tendency, or of a state allied to purpura or scurvy, would require, of course, full consideration and appropriate treatment. The extent of the ultimate injury to sight will usually depend upon the extent to which the perceptive elements of the retina have been compressed or disorganised, either by the bleeding itself, or by other changes consecutive to it.

c. *Arterial*.—Hæmorrhages which are distinctly arterial are not uncommon in the fundus of the eye, and can generally be distinguished without difficulty from the venous variety, not only by the colour of the effused blood, but also by the situation of the bloodpatch, and by its manifest relations to a small arterial branch, which may often be seen to have dwindled or closed beyond the point at which it has given way. Arterial hæmorrhages are mostly multiple, but of

small individual extent; and, when not in the immediate neighbourhood of the optic disc, are most commonly seen near the outer limits of the ophthalmoscopic field of view. They are generally attended by sufficient impairment of vision to occasion complaint, and thus to lead to their detection; but they seldom occasion blindness. They call for an examination of the urine for albumen, and, failing any evidence of renal mischief, they are chiefly important as indications of a weakened and brittle state of the arterioles, likely to lead to intracranial hemorrhage.

TREATMENT.—Arterial hemorrhages into the retina point to the necessity of diminishing, as much as may be possible, the strain upon the arterial coats, by such means as the avoidance of muscular exertion or mental emotion, and by seeking to diminish the quantity of the circulating blood by a diminution in the quantity of fluid ingested. Even when all precautions have been taken, arterial retinal hemorrhages are common forerunners of apoplexy.

6. Embolism of the Central Artery of the Retina. Embolism of the central artery of the retina, or of one of its branches, is a condition of not infrequent occurrence.

SYMPTOMS.—When sudden blindness of one eye occurs in a person who is the subject of valvular disease of the heart, the diagnosis can scarcely be doubtful, but the ophthalmoscopic appearances will suffice to remove doubt if it should exist. The immediate effect of the sudden arrest of the arterial circulation of the retina is to render that membrane opaque and of a milky whiteness, except over the macula lutea, where the absence of connective tissue prevents any such change from being produced. Here, and here only, the original transparency is retained, and the colour of the choroid is seen through, with the result that the macula appears as a cherry-red spot in the midst of a white surface. When not concealed by the opacity, the larger veins of the retina are diminished in calibre and contents, and their blood is sometimes broken up into detached portions separated by interspaces. The arteries are empty, and are either invisible or traceable as white lines of fibrous tissue in the general milkiness of the fundus. The disc is usually bleached, but it will sometimes happen that its condition may be temporarily obscured by arterial hemorrhage, occurring from some twig given off just below the seat of the embolus, and entering the eye independently.

The driving home of the embolus will throw upon such a twig the whole force of the circulatory *vis a tergo*, and may thus rupture it—an occurrence of which the writer has seen several examples. The blood so effused is usually absorbed in a very few days, revealing the white disc and the collapsed arteries, and removing any uncertainty which might have existed with regard to the diagnosis. The opacescence of the retina also disappears before long, and then only the secondary nerve-atrophy and the disappearance of the arteries remain to disclose the nature of the original affection. Embolism seems to be a perfectly hopeless condition, because there is no anastomosis between the retinal and other vessels of a sufficient extent to maintain a collateral circulation. The writer has met with one

instance in which only a sector of the field was affected, and with one in which embolism of a very small branch produced loss of sight over all the peripheral parts of the field, leaving central vision almost intact, but such cases are among the curiosities of ophthalmology, and complete and permanent loss of sight of the affected eye is the result which must always be anticipated.

7. Retinitis. Retinitis is commonly described as occurring in three chief forms, the *albuminuric*, the *sypilitic*, and the *pigmentary*; but the writer is inclined to believe that only the last of these three is a genuine retinitis, and that in the others the inflammation, if it should exist, is merely a secondary consequence of the irritation produced by the presence of adventitious deposits.

a. Albuminuric Retinitis. In the so-called albuminuric retinitis, the sequence of events appears to lend some support to the contention of Sir William Gull and Dr. Sutton, to the effect that the renal disease is not an original affection, but only a result of morbid or degenerative changes which are common to the whole of the small arteries of the body.

SYMPTOMS.—In many cases of albuminuria, the sight is not affected from first to last, and the retina remain healthy. In some, the retinal changes precede the appearance of albumen in the urine; and, in the majority, the renal and retinal changes are coincident. The retinal changes are of two kinds, namely, arterial hemorrhages, occurring in the fibre-layer, so that the blood-patches assume a floridated aspect with brush-like terminations, and the formation of white patches, either of cholesteroline deposit or of fatty degeneration, or of both combined, scattered irregularly over the fundus, but often grouped into a stellate figure around the macula lutea, and into an irregular ring around the disc. To these appearances are added, in some cases, those of swelling of the disc-margins with effusion into the retinal fibre-layer; and, when the last named appearances are present, there is always a far greater deterioration of sight than when they are absent. It is a matter of daily occurrence that the existence of renal disease is not suspected until impairment of sight leads to an ophthalmoscopic examination, and thus to the discovery of the retinal changes, and, in every hospital, cases which apply for relief to the ophthalmic department are constantly, on this ground, transferred to the physician.

TREATMENT.—The treatment of the renal maladies which produce albuminuria is in no way modified on account of the presence of a retinal complication, and the unfavourable prognosis which must generally be given as regards life throws into comparative insignificance the gradual failure of vision, which seldom proceeds to complete blindness.

b. Syphilitic retinitis. This is usually an incident of the most advanced stages of the disease, and is most frequently seen in persons who have been inadequately treated during the primary stage, but who have for some months or even for a year or two been free from symptoms.

SYMPTOMS.—Dimness of sight is then complained of, and the retina is found to present scattered patches of very irregular outline, and of a filmy whitish aspect. Such patches may

be more or less obscured by slight general turbidity of the retina itself, or of the vitreous body in its immediate vicinity, the latter condition being of itself almost conclusive of the nature of the malady.

TREATMENT.—The treatment must be greatly governed by the past history of the case, but may in most instances turn upon the use of iodide of potassium for the relief of the retinal troubles, followed by a sufficient course of mercury for the eradication of the syphilitic taint.

c. *Pigmentary Retinitis.* This appears to be a true inflammation of the retina, differing from the foregoing affections in that it attacks the percipient elements, instead of the fibre-layer or the connective tissue of the membrane.

Ætiology.—The subjects of pigmentary retinitis are of all ages, from nine or ten years to seventy, and, in some instances, the duration of the disease has been as much as twenty years, from the first appearance of the symptoms to their ultimate termination in blindness. As a rule, however, the patients are young adults, or persons not past middle age.

It is a remarkable feature of pigmentary retinitis that it almost invariably attacks more than one member of a family, and it has been said to be especially frequent in the offspring of marriages of consanguinity, but this statement is not borne out by English experience. During the last twenty years the writer has only met with one family in whom the malady had this history.

ANATOMICAL CHARACTERS.—From the extreme chronicity of its course, from its obstinacy, and from its peculiar anatomical distribution, pigmentary retinitis should probably be regarded, together with some forms of choroiditis, as having its analogies among some of the chronic skin-diseases rather than with any other retinal affection. It commences in a narrow annulus near the equator of the eyeball, and gradually spreads inwards towards the optic disc, the tissues affected are the percipient and pigmentary layers of the retina and the subjacent chorio-capillaris, which slowly become disorganised and matted together in one common and undistinguishable ruin. Coincidentally with the progress of the disease, pigment is deposited in the parts affected, and in the retina superficial to them, in the form of irregular lines and striations, and especially along the course of the main arterial branches. As the annulus of disease gradually closes in upon the macula, the optic disc undergoes atrophy of a kind which gives it a peculiar tint of whiteness, very readily recognisable when it has once been noticed, and the central vessels, both veins and arteries, dwindle in size.

SYMPTOMS.—The subjective symptoms are as characteristic as the ophthalmoscopic appearances. Over the region actually invaded, the percipient elements of the retina are destroyed, and the power to receive visual impressions is lost. The fibre-layer not being implicated, the conduction of impressions from parts of the retina more peripheral than the disease may remain unaffected; and hence we may have a blind zone surrounding the centre of the field of vision, and surrounded itself by a zone still more external,

in which dim vision is preserved. But the salient symptoms are two: the gradual contraction of the field of vision due to the progressive encroachments of the disease; and night-blindness due to the nerve-atrophy, which interferes with the conduction or perception of any but strong impressions. When these symptoms co-exist, when the field of vision is small and becoming gradually smaller, and when the patient, who can still see fairly in the daytime, can scarcely find his way about as dusk begins to fall, we may predict the ophthalmoscopic appearances with a very near approach to certainty. The optic disc will be unnaturally pale, and the fundus overstraw, towards the periphery, with irregular black lines and stripes, of which it is quite possible that none may be visible within that portion of the field of the ophthalmoscope which includes the disc.

DIAGNOSIS.—Pigmentary retinitis may possibly be mistaken for the most chronic form of glaucoma, on account of the contraction of the field of vision, but it may be distinguished by the absence of high tension, by the night-blindness, and by the pigmentation of the retina. It may also be mistaken for the atrophy of sclerotics, but only if the ophthalmoscopic examination is limited to the nerve-disc, to the exclusion of the surrounding parts of the fundus.

TREATMENT.—In the treatment of a disease so essentially chronic, it is difficult to arrive at any trustworthy evidence concerning the efficacy of a remedy, but the prolonged administration of iron, rather as a food than as a medicine, is at least of a certain degree of utility in arresting the progress of the malady. The preparation employed is probably not material, and some may be found to suit particular persons better than others, but the writer is accustomed to begin with the tincture of the perchloride, in doses of five minims, well diluted and given three times a day as part of a meal.

8. *Detachment of the Retina.* **SYNOPSIS.**—Sub-retinal droopy. This is a condition the causes of which have never been satisfactorily explained.

The first symptom which attracts the attention of the patient is the loss of part, usually either the upper or the lower part, of the field of vision; and it is manifest that loss of the upper part of the field means detachment of the lower part of the retina, and *vice versa*. Detachment is sometimes produced by a blow or injury, but more frequently it occurs without any assignable cause, either local or constitutional. One or both eyes may be affected.

The diagnosis of the disease is rendered easy by the ophthalmoscope, which exhibits the detached portion as a sort of floating prominence, projecting into the interior of the eyeball, generally bluish-white in colour, and crossed by the retinal blood-vessels.

The prognosis is very unfavourable in the majority of instances, and treatment is seldom effectual.

TREATMENT.—Cases have been recorded in which disappearance of the sub-retinal fluid, and restoration of vision, have followed prolonged confinement in the supine posture; and the occurrence of improvement after spontaneous rupture of the detached portion suggested to Von Graefe

the advisability of producing such a rupture by artificial means. Various operations have been undertaken for this purpose, and also for the evacuation of the sub-retinal fluid through a puncture in the outer tunics of the eye, and are said by those who have performed them to have been in a few instances partially successful; but the evidence in their favour is at present very feeble, and hardly establishes more than that attempts of such a nature may be made, if it is certain that the sight will be irretrievably lost in the absence of interference. The tendency of detachment, especially in the upper portion of the retina, is to increase until the whole membrane is elevated from the choroid, and vision is entirely destroyed. It must be borne in mind that detachment may be simulated, or may even be caused, by the growth of intra-ocular tumours, sarcomatous or gliomatous, which may demand the early removal of the eyeball. Such cases would be distinguished from simple detachment by the increased hardness of the eyeball, which the morbid growth would necessarily occasion, and which would be the more significant inasmuch as detachment alone is usually accompanied by diminished tension.

9. *Glioma*. This name has been given by Virchow to a malignant growth which has its origin in the neuroglia, or connective tissue of the nervous system, and which was formerly described as encephaloid cancer. When originating in the retina, it early produces loss of sight, and presently shows through the pupil as a substance of a primrose-yellow colour, by which the still transparent lens is pressed forward towards the cornea. It is chiefly a disease of childhood, and has been seen by the writer as early as the fifth week of infant life. It is liable, by superficial observers, to be mistaken for congenital or infantile cataract, an error which must be carefully guarded against, because the early and entire removal of the eye, together with as much of the optic nerve as can be reached, furnishes the only hope of preserving the life of the patient. When the operation is performed sufficiently early, it has in a few instances been completely successful, cases having been recorded in which no recurrence of cancer has happened after the lapse of years. In the great majority, however, recurrence and death have terminated the history.

10. *Sarcoma*. This differs from glioma in having its origin in the choroid, and in being of a darker colour, and sometimes pigmented or melanotic. It is at least equally malignant, produces similar symptoms, and requires the same treatment.

VIII. Diseases of the Choroid.—Diseases of the choroid, recognisable by the ophthalmoscope, are almost limited to certain chronic forms of inflammation and of atrophy; for, in any acute choroiditis, there is always too much turbidity of the vitreous body to allow the state of the membrane to be seen.

1. *Chronic Choroiditis*.—The chronic forms of choroiditis are remarkable for leading to an undue formation, or to a great displacement, of the choroidal pigment; and to the ultimate complete wasting and disappearance of the portions of the choroid which are affected, so that over

these portions there will ultimately be no choroid visible, and the ordinary red colour of the fundus will be replaced by the ivory whiteness of the inner surface of the sclerotic.

Chronic choroiditis may be divided into two chief varieties, the *disseminated* and the *diffused*. The *disseminated* occurs chiefly in children, and chiefly, perhaps exclusively, in those who are the subjects of inherited syphilis. It is seldom seen until its period of activity is past. A child is brought on account of defective vision, which has probably existed from birth or from a time but little subsequent to it, and the ophthalmoscope displays a number of small white spots, with black borders, scattered irregularly over the fundus of the eye. The white spots are patches of choroidal atrophy, and the black borders are rings of increased pigment-formation, by which the spots of inflammation, which must have been comparable to little pimples, have been surrounded.

TREATMENT.—Such cases admit of no treatment, except in the rare instances in which some active mischief may be detected, in the shape of small patches or spots in which effusion has not yet passed into atrophy, and in which such an antisyphilitic treatment should be employed as the state of the patient may otherwise permit or indicate.

Diffused choroiditis is more frequently an affection of adult age, and, although very frequently syphilitic, is not invariably so. It differs from the foregoing chiefly in the absence of any defined shape or precise limitation of the parts affected. In the early stages the choroid is seen to be troubled by congestion or effusion, and these conditions pass gradually into abnormal pigmentation and atrophy. The course of the disease may be very chronic and irregular, and different stages of it may be seen at the same time in different parts of the same eye.

The prognosis may in general be moderately favourable, for, although the choroiditis destroys the portion of retina immediately in front of it, its extension is very capricious and it may often be arrested in time to leave large portions of the eye, and especially the central portions, unharmed. When it occurs in the vicinity of the macula lutea, so as to imperil central vision, it is much more formidable than when confined to the more peripheral parts of the choroidal membrane.

TREATMENT.—Whenever there is a history of syphilis, this must be taken as the clue to treatment, and, if no syphilis can be discovered, the chief reliance must be placed upon rest of the eyes, occasional depletion from the temples by Hæmorrhoids leech, counter-irritation by blisters or setons, and such internal medication as the general state of the patient may suggest.

IX Diseases of the Vitreous Body.—Diseases of the vitreous body are as yet very imperfectly understood, and we know little more concerning them than that this substance is liable to become turbid in certain forms of acute general inflammation of the eye, and that it is sometimes rendered turbid, without inflammation, by the presence of floating films which may be readily seen by the ophthalmoscope, and which may be so numerous as to form a serious impediment to vision.

1. *Turbidity*. Turbidity of the vitreous is very

summon in syphilitic cases; but the films referred to are seen when no syphilis can be suspected. Their number, and their free movements, show that the vitreous must in great measure have lost its natural semi-solid consistence, and have become fluid; but little or nothing is known of their actual pathology.

TREATMENT.—The most effectual treatment for fluxion in the vitreous is usually diaphoresis by the subcutaneous injection of from two to four minims of a 10 per cent solution of hydrochlorate of pilocarpine, which may be repeated on alternate days. Local counter-irritation with iodine may also be practised, and iodide of potassium may be given internally in such doses as circumstances will allow.

2. *Musce Volitantes.* A phenomenon referred to the vitreous body is the appearance of the moving particles, or strings of beaded filaments, which are commonly called *musce volitantes*. True musce are known by the negative character that the particles which produce them cannot be seen by the ophthalmoscope; and by the positive character that they never so intervene between the eye and an object, however small, as to exclude the latter from view. They are seen most readily against a white field, as a white wall, or a white cloud, or in the illuminated field of a microscope when there is no object in view, and they float about with uncertain movements, but always a little out of the direct line of sight. They are occasioned by the filamentous framework of the vitreous body, and by the cell-nuclei or other irregularities upon the filaments. These bodies, without being opaque, yet differ in the precise degree of their transparency from the fluid which surrounds them; and hence they cast upon the retina shadows, which are then mentally projected outwards into space as floating objects. The projected shadows appear, of course, enormously larger than the microscopic objects which produce them, and the latter are wholly unimportant and of no morbid signification. Musce may be discovered by any person by the simple expedient of looking through a very fine perforation in a metal disc at a bright surface; and they are more conspicuous to some persons than to others, on account of the varying differences which may exist, in different eyes or in the same eyes at different times or under different conditions, between the index of refraction of the filaments and nuclei and that of the surrounding fluid. Moreover, by the operation of an obvious physical law, the more distant the particle from the retina, the larger will be its shadow upon that membrane, and the larger and more conspicuous will it appear. For this reason, and on account of the elongation of the myopic eyeball, musce are usually more complained of by the short-sighted than by others. They are often sources of great uneasiness to patients, but, when once their true character is known, they may be entirely disregarded as harmless appearances, the natural results of physiological structure. It is often important that the physician should be able to make their nature understood, in order that he may dissipate, once for all, the unfounded apprehensions which may be occasioned by their presence.

X. Diseases of the Eyelids.—The external surfaces of the eyelids, as parts of the common integument, are liable to all its diseases, and may thus participate in eczematous inflammation, in eruptions, and in the results of injury, besides becoming the seats of warts, moles, warts, and other growths. Among the diseases special to the formation of the eyelids, the most important are the variations of shape to which they are subject, generally from the contraction of inflammatory exudations but sometimes from perverted muscular action, the cystic tumours which are produced by obstruction of the orifices of meibomian glands; the inflammation of the follicles of the eyelashes, or blepharitis; spasmodic closure, from abnormal muscular contraction, and either patency or passive closure, from paralysis. Many of these affections are distinctly surgical, and others are only parts or symptoms of more general disorders.

1. *Blepharitis.* Blepharitis, or inflammation of the follicles of the eyelashes, has received a great variety of names from different writers, and is frequently known as *linea tars,* or, in its more advanced stage, as *lippitude*. The disease consists essentially of an inflammation of the lining membrane of a hair-follicle from which an eyelash springs.

SYMPTOMS.—The first manifest symptoms are a small swelling close to the edge of the eyelid, generally of the upper lid; and the formation of a crust around the bases of the cilia which proceed from the swollen part. The swelling does not extend farther up the lid than to the breadth of about a line, but it soon spreads along the border until the whole length is involved, and it usually spreads also to the lower lid, manifestly in consequence of the contagious character of the discharge. If the crust is removed, and if the part from which it springs is magnified and carefully examined, it will be seen that the mouths of the follicles are somewhat open, no longer fitting closely to the issuing hairs; and, in a few moments, a clear fluid will be seen to exude, and speedily to dry into a crust or film, which covers the opening as if with a varnish. Many of the hairs in the affected follicles are loosened, and fall readily, or may be removed painlessly by slight traction. If the cure is neglected, the follicles are before long destroyed as hair-bearing organs, so that the lost cilia are no longer reproduced, and, at the same time, the exudation which constitutes the subcutaneous swelling of the lid-margin begins to undergo contraction, and in this way gradually everts the cartilage of the lid. The edges of the lids become red, swollen, and unsightly; the lachrymal puncta are displaced outwards in such a manner that they can no longer take up the tears; the eyes have lost the protection of the lashes, and are exposed to numerous sources of irritation from atmospheric particles and other causes, so as to be especially prone to conjunctival and corneal inflammations; and these results are almost incurable. It is therefore very important that blepharitis should be effectually treated in its early stages, when, if only due care be taken in the selection and use of remedies, it is an exceedingly trivial affection.

TREATMENT.—The most essential part of the

treatment is to remember that the secretion which forms the crust is of such a nature that it is not very easy of removal, and that while it remains *in situ*, no remedies, however judiciously chosen, can obtain access to the parts really affected by the disease. The crust is composed partly of the already mentioned secretion from the inflamed surfaces, partly of the greasy secretion of the meibomian glands, and it is the admixture of the latter which renders the crusts difficult of removal by water alone. A solution of bicarbonate of soda, of the strength of five grains to the ounce of warm water, will remove them readily; and this solution should be applied in such a manner as to soak into the crusts and loosen them thoroughly before any attempt is made to detach them. As soon as they are detached, the surface beneath should be gently dried with a morsel of absorbent rag, and then an astringent should be applied immediately, so that it may find its way down into the depths of the hair-follicles, and may thus reach the seat of the malady. The best astringent is generally the ointment of the precipitated yellow oxide of mercury, or Pagenstecher's ointment, already recommended for the cure of ulcers of the cornea; and this may be applied to the affected part by the tip of a finger. If amendment does not speedily follow, it may be suspected that the crusts have been imperfectly removed, or the applications imperfectly made, and it will be well for the practitioner personally to superintend the process. When this has been done, if the affection continues obstinate, some other astringent should be tried, and the nitrate of silver is among the best for this purpose. Amendment of the lid margin may generally be quickly produced; but the disease will for a long time lurk in the depths of the follicles and the treatment must be continued until all subcutaneous swelling has disappeared from the lid-margins. Unless this be done, speedy relapse is inevitable, the inflammation soon creeping out of the follicles again and recovering the ground of which it had been deprived. Such a result is constantly seen in hospital practice, in spite of all efforts to guard against it, and, in undertaking the cure of blepharitis, it is always desirable to warn parents of the perseverance which will be required, and of the great importance of obtaining a radical cure. There can be no doubt that blepharitis is exceedingly contagious through the medium of its secretion, conveyed upon sponges, towels, or fingers, and this should be fully recognised whenever it attacks children who are attending a school. The name 'tinea tarsi' may perhaps be taken as the expression of a belief that the disease is allied to tinea tonsurans, and that it is produced by the growth of a parasitic fungus. The writer does not at present see any sufficient ground for the adoption of this opinion.

2. *Entropion and retroponon.* Incurvation and excoriation of the eyelids may be looked upon as purely surgical malades. The former exposes the eye to injury from the irritation of intumed eyelashes (*trichiasis*); the latter from foreign bodies of various kinds.

TREATMENT.—The remedy for both, when any is practicable, must usually be sought in a surgical operation. An exception depends upon the fact that ectropium is sometimes produced

by paralysis of the facial nerve, which renders the orbicularis muscle flaccid and powerless, and permits the lower lid to fall downwards under the influence of gravity. The cure of the general nerve-affected may restore the power of the muscle, and may in time lead to complete recovery of the natural position of the lid. In such cases, even if electricity does not form part of the general treatment, of the paralysis, it may generally be applied with benefit to the orbicularis.

3. *Blepharospasmus.* This term is generally employed to denote an intermittent closure of the eyelids by an involuntary action of the orbicularis in response to some concealed source of irritation, and is thus broadly distinguished from the spasm which accompanies photophobia.

SYMPTOMS.—The spasm is most liable to occur in circumstances of mental excitement. Thus, in one of the writer's patients, who was a skilful cook, the eyes were apt to close, and to remain closed for some minutes, at the critical period of an important dish. Another patient was a schoolmistress, and the spasm would interrupt the progress of a lesson to a class, being doubtless to some extent excited by the dread of its occurrence. In a third case, the patient being a gentleman habituated to riding and driving, the spasm would be excited by physical irritants, such as wind or dust, and, almost certainly, by circumstances which required the eyes to be wide open as a condition of safe guidance. The motor nerves appear, as a rule, to be merely the passive conductors of a reflected impulse, and the trouble seems usually to be dependent upon a morbid condition of the fifth, or upon a source of irritation in some peripheral part from which a twig of the fifth passes to the centre.

TREATMENT.—In the treatment of such cases, it is sometimes possible to find the twig which conveys the impression, that is to say, to discover a point where pressure, sufficiently firm to arrest conduction, will at once relax the spasm. Such points should be looked for at the supra-orbital notch, over the malar bone, and in any other situation suggested by special circumstances, and, if a point at which pressure will arrest the spasm is discovered, we learn at once by what branch of the fifth, and therefore approximately from what region, the irritation is conveyed, and where its source is to be sought for. If nothing can be discovered by careful examination, decayed teeth, accumulations of cerumen in the ears, and conjunctival granulations are possible conditions which should be looked for, and which should receive attention if they are found. When all other treatment has failed, the spasm has sometimes been stopped by subcutaneous section of a sensory nerve; and this may always be practised hopefully if the spasm can be arrested by pressure on some definite spot, which must then serve for the guidance of the knife. If no such spot can be found, section of the supra-orbital nerve, and next of the subcutaneous malar, may be attempted, since neither of these are sufficiently important for their temporary disablement to be set against even the possibility of relief from a very distressing affection. In some cases, however, it would appear that the mischief must be central,

and that no section of an afferent nerve can be useful. The division of the motor nerves of the ocular muscles, if it could be successfully accomplished, would produce a paralysis even more injurious than the spasm; and the cases in which the latter is due to central irritation or other trouble, unless they can be relieved by medicine, and by the rectification of whatever may be manifestly wrong in the condition of the patient, offer very small hope of improvement. See FACIAL SPASM.

4. *Ptosis*.—*Ptosis* is a condition of permanent passive closure of an upper eyelid as a consequence of paralysis of its levator muscle, or it may happen in consequence of this muscle having been torn from its attachment to the tarsal cartilage, so that it can no longer modify the position of the lid.

SYMPTOMS.—Paralytic ptosis may be either partial or complete, according to the degree of the nerve-affection; and as the levator palpebre is supplied by the third nerve, which supplies also the superior, the internal, and the inferior rectus, as well as the inferior oblique, the sphincter pupillae, and the ciliary muscle, ptosis is usually accompanied by paralysis of one or more of these muscles. When they are all affected, the eyeball is turned outwards by the action of the external rectus, and is immovable in other directions excepting feebly by the superior oblique. The pupil is dilated, and the power of adjusting the eye for near vision is impaired or lost, although when the lid is raised, near objects can still be distinctly seen by the aid of a convex lens. When all the muscles supplied by the third nerve are affected, the inference is that the cause of paralysis is acting upon the common trunk of the nerve; and such a cause is not unfrequently the presence of periosteal swelling at the sphenoidal fissure. If only some of the muscles are affected, the inference is that the cause of the paralysis is either limited to the central nuclei of origin of certain filaments, or else that it is situated anteriorly to the division of the main trunk into the branches which proceed to different parts;

and it is conceivable that the limitations of the paralysis may point, with tolerable certainty, to the precise locality of the disorder.

The causes of ptosis, as of other paralytic affections of single cranial nerves, apart from injuries and the pressure of morbid growths, may almost be reduced to syphilis and to impaired nutrition of the centres, the latter usually connected with hard mental work and worry. In every case, evidence of syphilis should be carefully sought for; and, if found, should determine the nature of the treatment, as it will also of the prognosis, which, in such instances, may be generally favourable. In cases of the second class, where there is no evidence of syphilis, and where the symptoms point to general impairment of nervous energy, the administration of iodide of potassium, in combination with tonics, will sometimes be useful, but the main reliance must be placed upon rest, good living, and external surroundings favourable to the restoration of health.

5. *Diplopia*.—Double vision, although it has no proper relation to the subjects treated of in the present section, is yet so far allied to ptosis that, when occurring suddenly, it is almost always an effect of paralysis of or paresis either of the sixth nerve of one eye, supplying its external rectus, or of the branch of the third which supplies its internal rectus. In the former case the affected eye will deviate inwards, and will have limited range of movement towards the outer canthus; while in the latter case these conditions will be reversed.

As regards the causes and treatment of these limited forms of paralysis, there is nothing to add to what has already been stated about ptosis. It is sometimes desirable, while the diplopia continues, to exclude the deviating eye from vision by a shade, an opaque spectacle glass, or other suitable contrivance, on account of the vertigo and uncertainty of gait which may be occasioned by the double images.

R. BRIDENELL CARTER.

F

FACIAL PARALYSIS.—SYNON: Paralysis of the Portio dura, Bell's Paralysis.

DEFINITION.—Paralysis of the muscles of the face, due to disease or injury of the nucleus or fibres of the portio dura of the seventh pair of nerves.

Above the nucleus, in the middle of the pons, the motor tract decussates and mingles with that from the arm and leg, damage, therefore, in the upper part of the pons, crus, corpus striatum, or hemispheres produces facial paralysis as a part of hemiplegia. This paralysis, on the same side as in the limbs, is partial only, affecting chiefly the muscles of unilateral use (as the zygomatic and muscles about the angle of the mouth); and

very little those of bilateral use, in the upper part of the face (orbicularis palpebrarum, and frontalis). In this article paralysis from damage to the fibres or nucleus of the nerve will alone be considered.

ÆTIOL. &c.—(1) The most common cause of facial paralysis is damage to the nerve as it passes through the narrow canal in the temporal bone. There the slightest effusion will cause pressure on the nerve. Such effusion may be due to exposure to cold—'rheumatic'; 'contiguous bone-disease—caries; syphilis; or hæmorrhage; but often occurs without discoverable cause. Cold has been supposed to act most commonly by paralyzing the peripheral nerve-twig, but

this is rarely, if ever, the case; since in all cases lasting more than a few days, evidence of changed nutrition may be detected in the nerve-trunk as it emerges from the stylomastoid foramen. (2) Injury to the nerve outside the skull by blows, or incised wounds, or parotid and other tumours, is an occasional cause. (3) Within the skull the nerve may be damaged by meningitis, acute or chronic, and especially by syphilitic inflammation, or by pressure of neighbouring growths. The radicular fibres within the pons, or the nucleus beneath the fourth ventricle, may be damaged by hemorrhage, softening, or growth affecting that part.

Double facial paralysis is very rare, and is due to damage to the nerves at the base of the brain from meningitis, or symmetrical syphilitic disease; or to an affection of the nuclei by disease of the pons, or by loss of function of the nerve-cells composing the nuclei. Syphilis and diphtheria are the most common antecedents.

SYMPTOMS.—The onset of facial paralysis is usually gradual, occupying from a few hours to three or four days in its development. It is found, for instance, one morning that in drinking the fluids run out of the side of the mouth; the face is noticed to be a little unsymmetrical; at night the eye cannot be completely closed; and next morning the paralysis is found to be complete.

In complete unilateral facial paralysis all the muscles on one side of the face are paralysed. At rest, the smooth forehead and lowered angle of the mouth are the chief indications, but on movement the difference between the two sides becomes very marked; the one half of the forehead moves alone in frowning or elevation of the eyebrow. The eyelids cannot be brought together, and in the attempt to close the eye the eyeball is rolled upwards so that only the sclerotic appears between the gaping lids, the patient commonly imagining that the eye is shut. During sleep the eye remains open. In smiling, the lips may be displaced altogether to the healthy side, from the unopposed action of the zygomatic muscles, the nostril of the affected side cannot be dilated, the upper lip cannot be raised, the cheek flaps loosely from the relaxation of the buccinator, and from the same cause food accumulates between the jaws and the cheek. Whistling is impossible, from the paralysis of half of the orbicularis, and the lips cannot be approximated sufficiently even to permit of a candle being blown out. When the lesion is between the origin of the large petrosal and the chorda tympani nerves, taste is partly or entirely lost in the front of the tongue. The loss of power of recognising acid and saline substances is most marked, but bitter and sweets are also not tasted in this part. In rare instances loss of taste has followed division of the nerve outside the skull. When the disease is above the origin of the great superficial petrosal, the uvula is said to be oblique, from paralysis of its muscle, and the palate to be motionless on that side. Of this there is much doubt. Obliquity of the uvula is common under normal conditions. The writer has never seen paralysis of the palate or uvula in these cases.

In some cases giddiness marks the onset of

facial paralysis. In less severe cases there may not be complete loss of power, but the loss is at first pretty equally distributed over all parts of the face.

In cases which recover, some return of power takes place in from a week to two months, and improvement is usually earliest in the upper part of the face, the power of frowning, winking, and closing the eye being almost regained, that of moving the lip and mouth returning last. Even after several months of immobility, recovery may take place, but in these cases it is rarely complete, and a troublesome condition is apt to supervene, some of the muscles, especially the zygomatici, become shortened in late rigidity, and hence at rest the naso-labial wrinkle is deeper on the paralysed than on the healthy side, although the possible movement may be much slighter. This condition sometimes comes on rather suddenly. If, in addition, a troublesome associated over-action of muscle manifests itself, whereby the orbicularis palpebrarum and the zygomatic and other muscles about the mouth act together, in smiling the eye shuts, and on closing the eye the mouth is drawn upwards.

The electrical condition of the muscles is very important. It is thus always seen in paralysis from nerve-lesion. The muscles, after a day or two of slightly increased irritability to both faradisation and the slowly interrupted battery current, lose gradually their irritability to the former, retaining that to the latter, and even exhausting to it increased irritability, so that they act to a smaller number of cells than on the healthy side. In the nerve, on the other hand, the irritability is lost to both forms of electricity, this loss proceeding *pari passu* with the degeneration which follows separation of the nerve from its nutrient centre. In slighter and more transient forms of facial paralysis the change in irritability of muscle and nerve may be slight, but even in most, which last but a few days, a slight change in irritability may be discovered.

DIAGNOSIS.—The diagnosis of facial paralysis is easy. It is important to observe all the muscles of the face, and to ascertain the electrical reaction, in order to determine whether it is the variety now described, or is cerebral and part of an unnoticed hemiplegia. The recognition of the place of the lesion is less easy. When within the pons, it is often associated with paralysis of the sixth nerve, or with hemiplegia of the opposite side from damage to the fibres from the limbs. At the base of the brain the auditory nerve is usually affected at the same time. Where there are no other paralyses, the disease is probably within the long canal. Deviation of the uvula is a guide of most doubtful value. Special inquiry should be made for ear-disease, for syphilis, or for a blow.

PROGNOSIS.—The majority of cases of facial paralysis are due to rheumatic affection of the nerve, and recover, but the duration of some of these is considerable. In recent syphilitic cases the prognosis is good. In cases of the temporal bone and in intracranial disease, unless syphilitic and recent, the prognosis is less favourable. Whatever be the cause, the electrical reaction of the nerve and muscles affords valuable informa-

tion, since is proportion to the slightness of the change in relation to the length of time the symptoms have lasted, will the degree and duration of the affection be less.

In double facial paralysis the probability of central mischief will render the prognosis less favourable, but recovery may be hoped for if there are no symptoms of disease damaging structures contiguous in position, and not merely related in function, and if the disease be of short duration.

TREATMENT.—The treatment of facial paralysis will depend on the probable cause. When due to the effects of cold, hot fomentations to the side of the head and face may be employed in the early stage of the affection, and afterwards counter-irritation by blisters behind the ear. At first, diuretics and small doses of iodide of potassium, and subsequently tonics, are useful. Electricity to the muscle and the nerve is of great service, faradisation should be used if the muscles will respond to it, if not the voltaic current, slowly interrupted by a commutator, or by the negative pole being moved over the individual muscles, and only such strength being employed as shall produce distinct muscular contraction. If the tardid irritability be lost at first it will return as the muscles recover, and faradisation should then be employed. If electricity does no more, it keeps up the nutrition of the muscular fibres and aids the recovery of function in the nerve. Ultimate recovery is thus more speedy and more complete than without local treatment. Rubbing may be employed, the individual muscles being subjected to a process of gentle shampooing. The treatment of the late contraction which occurs in severe cases is often difficult. Faradisation of the opposite side of the face has been suggested, but can scarcely be of service. The zygomatic muscles may be elongated a little by frequent gentle traction and the other contracted muscles should be gently rubbed so as to lengthen them. Inunctions of olate of morphia may be tried. The muscles that are contracted should not be faradised. The condition usually lessens after a time, but often remains for many months, or even years.

Where facial paralysis is due to syphilis, it usually readily yields to antisyphilitic treatment, if recent, but even here electricity is useful, since degeneration of nerve and muscle rapidly occurs. In intracranial disease the treatment of the facial paralysis is usually subordinate to that of its cause. When there is indication of sudden and increasing mischief at the nucleus of the nerve, galvanism must be employed with caution.

The treatment of double facial paralysis presents no special points for consideration.

W. R. GOWERS.

FACIAL SPASM.—**SYNON:** Mimic cramp. *Fr. Tic convulsif.* When affecting the eyelids, *Elephasasmus*; *Nictitation*.

DEFINITION.—Spasm, sometimes tonic but more often clonic, involving some of or all the muscles supplied by the facial nerve.

ÆTIOLOGY AND SYMPTOMS.—Spasm in the face may be part of a wider convulsive movement, as

in epilepsy, hysteria, chorea, or torticollis, diseases dependent on central change. Secondly, it may be due to irritation of the trunk of the facial nerve by growths, pressure, or caries of the temporal bone. Spasm of this form may follow facial paralysis. Thirdly, it is very commonly reflex, produced by the application of cold, by intestinal worms, or especially by some disease or injury of the fifth nerve. Affections of the eye frequently lead to spasmodic closure of the lids—*blepharospasm*. Lastly, in other cases no cause can be assigned for it, especially in the local clonic spasm affecting the eyelids—one or both—and known as involuntary winking or *sartation*. The latter form is seen especially in neuritic persons; in nervous children it is not uncommon, and in hysterical girls. It is markedly increased by emotion and attention. All forms cease during sleep.

PROGNOSIS.—The prognosis of facial spasm is good, if the cause can be discovered. Where there is no discoverable source of reflex irritation the affection is often most obstinate.

TREATMENT. General tonics and local sedatives are the most important elements in the treatment of most forms of facial spasm. When irritation affects the fifth or the facial nerve, counter-irritation by blisters is useful. A careful search must be made for reflex or other causes, and if possible they must be removed, decayed teeth extracted, and neuritis relieved. When there are tender places in the course of the fifth nerve, pressure on which stops the spasm, much improvement can usually be obtained. Morphia, belladonna, and acetate are the best local sedatives, the former may be used as a hypodermic injection or by inunction. Arsenic may be injected in some cases with advantage. Iron and quinine are useful, especially the latter. Bromides and phosphorus are of little value. Where the affection runs into an habitual movement, facial gymnastics may be of service. A weak voltaic current, applied from the ear to the muscles, unbroken, may do some good; but it rarely, if ever, effects a cure. The same is true of the application of voltam to the sympathetic. See EYE, AND ITS APPENDAGES, Diseases of. W. R. GOWERS.

FACIES HIPPOCRATICA (Latin).—A peculiar expression of the face, so named from having been graphically described by Hippocrates. It is most strikingly observed in persons exhausted by copious discharges, as in cholera, by prolonged wasting diseases, or by starvation; and especially before impending death. It is thus described by Hippocrates:—'A sharp nose, hollow eyes, collapsed temples; the ears cold, contracted, and their lobes turned out; the skin about the forehead being rough, distended, and parched, the colour of the whole face being green, black, livid, or lead-coloured.'

FACIES, Examination of.—An examination of the facies frequently affords valuable evidence of the condition of the organs engaged in the process of digestion, and furnishes important data on which to found a diagnosis, and suggest a rational treatment. Not only may structural changes in the alimentary tract be discovered, but also the completeness of action of the various

digestive juices be recognised. As with the examination of the renal secretions, a previous knowledge of the healthy characteristics is an essential; that being granted, the investigation may be pursued on the same lines in both cases, as regards the general, microscopic, and chemical characters. Since, however, these characters are more directly dependent on the ingesta, and less upon the excretions, their examination cannot be so valuable an index of tissue-change as is the investigation of the urine.

1. Physical examination.—**1. QUANTITY** This is extremely variable. Taking the normal average for an adult to be about 5 ounces daily, it may vary from $2\frac{1}{2}$ to $10\frac{1}{2}$ ounces. The quantity would seem to bear no relation to the size or weight of the individual, but is rather influenced by the quantity and kind of food, and the activity of the secretions of the alimentary canal. As a rule, the amount is increased by a vegetable diet. In children it would seem the total daily amount is relatively slightly greater, whilst in old age there is an absolute diminution. When in disease the quantity is increased it is chiefly of the fluid portion, whilst a diminution affects both the solid and fluid parts. Tea is said to diminish the quantity of the fæces (Chambers). See CONSTIPATION, and DIARRHŒA.

2. CONSISTENCE AND APPEARANCE.—Departures from the normal cylindrical shape are frequent, and depend very much on the existence of constipation or diarrhœa. In infants the evacuations should be uniform and of a pappy consistency. The contents of the bowels pass from a semifluid condition in the ileum to the firmer state in the colon, mainly from an absorption of fluid constituents; should there be any delay in the passage the motions are liable to become hard and nodular (scybala), and this may occasionally be extreme, the fæces having all the appearance of sheep's dung, and being passed with considerable pain. On the other hand, an increased frequency of action of the bowels (diarrhœa), is associated with motions of all degrees of fluidity. This is very marked in the various forms of irritation to which the intestinal mucous membrane is liable, from the simple effects of a saline purge to the extreme conditions of ulceration, as in typhoid fever or dysentery.

The existence of hæmorrhoids, rectal growths, or an enlarged prostate, may be recognised by groovings and marks on the excrement. Among drugs, iron and vegetable astringents will render the fæces hard and firm. Occasionally the motions are passed in a fermenting condition, due to the presence of sarcine, and present a frothy brown, or yeast-like, appearance, similar to certain vomits.

3. COLOUR.—This is dependent on the bile-pigments, and is subject to considerable variation even within the limits of health. The usual brown colour becomes much darker if long retained, or with an exclusively meat diet, and pale yellow with milk food, as seen in infants, and tends towards a greenish tint when vegetables form the bulk of the food.

The most important abnormal causes affecting the colour are the following:—

(a) *Bile.*—Obstruction to the passage of bile into the duodenum, causing the motions to be

clay-coloured, or patty-like. Such evacuations are often combined with distinctly bile-coloured fluid, which is secreted by the mucous membrane of the bowels from the bile-laden blood, &c., as is the coincident high-coloured urine. In extreme anæmia and the rickety cachexia the stools are usually pale from deficiency of bile-pigment.

(B) *Blood.*—This may either appear as streaks or patches of pure blood on the surface of the motion, as is the case when hæmorrhoids or ulceration of the rectum exists. Or the fæces may be of a uniform brick-red or almost black colour when there has been a hæmorrhage from the intestinal surface, the blood becoming intimately mixed with the fæces, and more or less affected by the sulphurated hydrogen of the bowels, forming a black sulphide of iron. If the blood has escaped into the stomach the action of the gastric juice on the blood-pigments is such as to convert the fæces into a tarry looking material of a very characteristic appearance *See MÆLÆNA.*

(γ) *Articles of Diet, Drugs &c.*—Among the former may be mentioned spinach, coffee, claret, and porter, which confer on the excrement their characteristic tints. Among the latter, logwood and charcoal may be detected by their colour in the fæces. Salts of iron and bismuth, by being converted into the sulphides, render the motions black or olive-green.

The exact cause of the green stools so frequently seen in children during dentition is uncertain, whether it be due to direct conversion of blood that has been slowly effused into the alimentary canal, by the digestive juices and gases, or whether it be bile-pigment altered by these same agents. Inasmuch as the bilinary colouring matters are more or less directly obtained from the hæmatin of the blood, the original source of this green colour (biliverdin) is the same in both cases. But its occurrence cannot be certainly taken as an indication of increased secretion of bile, for it possibly may depend on a diminished absorption.

4. ODOUR.—The characteristic odour of the fæces is in part due to certain substances developed during pancreatic digestion and partly to special secretions from the glands of the colon, as well as to certain articles of diet such as garlic, or of medicæ such as sulphur. Disturbance of either of the above conditions will affect the odour. Absence of bile from the alimentary canal, by interfering with the pancreatic digestion, and also by the want of its own special antiputrescent power, is accompanied with very ill-smelling motions. In this case the fæces may be almost putrid, which is not a normal condition. This state is still more marked in certain diseases of the colon, as dysentery, when the evacuations are of a most foul and acid character. In children the alvine discharges are very apt to be offensive from errors in diet, or to emit a peculiar sour odour.

5. FOREIGN BODIES.—By inspection of the evacuations we may discover:

(a) *Substances accidentally swallowed*, such as coins, pins, &c.

(b) *Indigestible food*, such as fish-bones, cherry-stones, &c.

(c) *Undigested food.*—Portions of food that

have escaped digestion. In certain severe disturbances of the digestive functions some of the food may be passed scarcely, if at all, altered soon after ingestion, and may be easily recognised. This condition, known as lenty, is especially prone to occur in the intestinal catarrh of young children during dentition.

(d) *Fatty or soapy masses*.—These may follow the administration of oils—castor, cod-liver, &c. They are more likely to occur when the biliary and pancreatic secretions are deficient, and appear as nodular masses, as large as filberts, or as cylindrical pieces, which have been compared to mucroni. Curdy lumps derived from milk are often met with in infantile diarrhœa.

(e) *Fæces*, such as segments of tenia, the various round-worms, or the contents of hydatid cysts that may have burst into the canal.

(f) *Gall-stones, intestinal concretions, mucous or membranous casts of the intestines* portions of bowel sloughed off from intussusception, &c.

II Microscopical examination.

METHOD.—The evacuations, when of ordinary consistency, require to be shaken up with two or three times their bulk of distilled water and allowed to stand. This may be repeated several times, and the washings successively submitted to microscopic examination as well as the final sediment. When the discharges are very fluid this process is not needed.

CONSTITUENTS.—The usual microscopic constituents of the feces are—

(a) *Undigested and indigestible residues of the food*. Such are starch cells woolly fibres particles of husks of corn and other seeds, muscular fibres with their characteristic structure and generally bluish-stained, shreds of elastic tissue and fibres from the blood-vessels; portions of cartilage, hairs.

(b) *Epithelium*.—This is derived from the mucous membrane of the canal. The cells may be more or less distinct and separate, or form by cohesion amorphous yellowish masses which constitute a considerable portion of the solid matter.

(c) *Oil*.—Occasional oil-globules are seen.

(d) *Crystals of triple phosphates*.

(e) *Amorphous granular matter*.

Since the nature of the food varies so widely it is impossible to state anything in regard to the relative proportions in which these objects occur. In certain states they are found absent or in excess. When from any cause the fats are imperfectly digested they may be recognised in the discharges. Crystals of ammonio-magnesian phosphates are very abundant in typhoid evacuations. The spores of fungi, and the ova of intestinal parasites, and the hooklets of hydatids may be met with, and bacteria would seem to be very frequent, possibly in connection with pancreatic digestion.

III. Chemical examination.—The imperfect knowledge we possess of the actual chemistry of the tissues and secretions, with the exceeding variety in the composition of the ingesta, prevents our obtaining, from any analysis of the feces, much information of a practical character. It is seldom if ever that such examination furnishes evidence of primary importance, as does the urine; it is only occasionally that the results

correspond to what other signs and symptoms indicate to be the case.

On an average the feces contain about 23 per cent. of solid matter to 77 per cent. water, but this proportion is liable to the widest variations both in health and disease. Thus in cholera-stools the solid residue may be but a few grains per pint.

1. SPECIAL CONSTITUENTS.—Two bodies—*œcretin* and *stercorin*—have been described as characteristic of the feces. Both are non-nitrogenous, crystallizable, non-saponifiable bodies, the former containing sulphur. They differ in their crystalline form and solubility in alcohol and ether. They appear to be closely related to *cholesterin*, with which in many points they agree. It is found that when the bile which normally contains *cholesterin* is prevented reaching the intestines, that neither of these bodies occur in the feces, and that they are also absent, being replaced by *cholesterin* in the meconium, and in starving and hibernating animals, when there is no obstruction in the bile-flow. Flint considers about ten grains per diem to be the average amount of *stercorin* and the *œcretin* of Marcet to be about a fifth of that. *Cholesterin* itself, except in very small quantities, cannot be regarded as a normal constituent of the feces, but the precise significance of its occurrence is uncertain.

2 FATTY ACIDS, FATS AND SOAPS.—*Excretoric acid*, one of the fatty series, is described by Marcet as a constant ingredient. Free stearic and margaric acids only occur in minute proportions, in ordinary circumstances, but are readily increased to considerable amounts when the alkaline secretions of the liver and pancreas are prevented entering the intestines. A vegetable diet is also said to increase them. *Butyric acid* does not seem to be of normal occurrence in human feces. The presence of neutral fats in the excrement may be taken to indicate that there has been excessive ingestion or a diminished digestion, since under ordinary circumstances they would be absorbed. The soda and potash soaps ordinarily formed by the ingested fats with the bile and pancreatic juices should be in great part taken up by the lacteals; but a portion meeting with any lime or magnesium salts that may be in the alimentary canal, form with them insoluble hard soaps which are passed in the feces. Marcet describes a case in which a large quantity of bi-stearate of soda was voided, the bile and pancreatic juices having been absent from the intestine.

3 SALTS.—They form but a small amount, and are chiefly the earthy and triple phosphates, with small quantities of iron and silica; there is a marked absence of chlorides. When the stools are very alkaline the triple phosphates may be very abundant, and in cholera-discharges the whole amount of salts is largely increased, there being nearly an ounce in every hundred fluid ounces of evacuation, a large proportion of which consists of chlorides.

4. PIGMENT.—The ordinary colour of the feces is due to a modification of the bile-pigments, but the exact nature of the change is unknown. The absence of colour from the discharges when there is an arrest of bile-flow has been referred

to; but though clay-coloured stools as a rule do indicate such arrest it is not invariably so, for the writer has met with a case in which normally coloured feces in the small intestines were absolutely deprived of their pigment in passing over a diseased portion of the lower end of the ileum.

5. **Mucus, Albumen, &c.**—There is usually a small amount of mucus passed with the feces, and this may be considerable in amount, resembling jelly, when any irritation of the rectum or colon exists, or occasionally more condensed, forming cylindrical casts of portions of the canal.

Albumen as such can scarcely be looked upon as a normal ingredient of the evacuations, but the fluid part of cholera-stools, which resembles blood-serum in composition, contains a very appreciable quantity.

Ferments similar in action to ptyalin and pepsin are described as existing in the feces, but how they may be modified in disease is quite unknown.

Next to the undigested and indigestible residues of food, the feces may be regarded as an excretory channel of certain materials from the blood by means of the bile. The other digestive juices are probably re-absorbed. As an index, however, of bile-excretion the feces are very unreliable, inasmuch as no ingredient of the bile is normally found in them as such. Whether pigment, bile-acids, or cholesterin, they all undergo a change. The occurrence, therefore, of any of these materials in the alvine discharges may be taken as evidence that the changes in the biliary constituents which should take place in the intestines are interfered with.

6. **REACTION.**—As a rule, the reaction of the feces is acid, showing that there is no putrid decomposition. Occasionally, however, it may be slightly alkaline. When the strongly alkaline secretions of the liver and pancreas are prevented through obstruction or disease from entering the canal, the motions may be strongly acid from the existence of free fatty acids.

For the Diagnostic Characters of the Fæces in disease, see STools, Characters of.

W. H. ALLCHIN.

FÆCES, Involuntary Discharge of.—Under normal circumstances the feces are retained within the rectum by the closure of the sphincter ani. When defecation takes place the sphincter is relaxed, there is increased peristalsis of the lower bowel, and there is pressure on the intestines, from the contraction of the expiratory muscles with the glottis closed. The nerve-governance of these three phases of the act is different in each case. The contraction of the abdominal muscles is mainly due to an effort of the will. The activity of the colon and rectum is reflex, from irritation of the intestinal ganglia by the accumulated feces. Lastly, the relaxation of the sphincter depends on the inhibition of the tonic centre in the lumbar enlargement of the spinal cord, such inhibition being brought about either in a reflex manner from the rectum or directly from the cerebral centres. It is obvious that the relaxation of the sphincter is the most important stage in the act, for until that takes place no discharge can occur. Up to a cer-

tain point the increased peristalsis and pressure on the bowels may be resisted by a voluntarily increased contraction of the sphincter, but at a certain stage the inhibiting influence is exerted, and relaxation results. Since this influence is beyond the control of the will, it would follow that the chief causes of the involuntary discharge of the feces are to be found in those conditions which interfere with the normal tonicity of the sphincter. At the same time, any circumstances which may increase the pressure of the abdominal muscles or the activity of the bowels much beyond what ordinarily occurs, may lead to an involuntary discharge.

Ætiology.—The causes of involuntary discharge of feces may be thus tabulated:—

1. *Volent contraction of the expiratory muscles*, such as may be induced by strychnia-poisoning. It is of rare occurrence in tetanus.

2. *Increased peristaltic action of the intestines*. This is chiefly dependent on causes of irritation situate in the bowels themselves, such as inflammation or ulceration of the walls, irritating contents, worms, &c. Extreme fluidity of the feces is frequently sufficient to induce their partially involuntary discharge, and is noticeable in the diarrhoea of infants and children.

3. *Abnormal relaxation of the sphincter ani*. As already said, the previous mentioned causes are powerless to produce the discharge of the feces until the sphincter yields, and how far the sphincter may relax as a result of their efforts, or independent of them, is not easy to determine. The nervous influence emanating from the lumbar centre which normally determines the tonic state of the sphincter may be inhibited—

a. *Reflexly*, as from worms, fissure of the anus, or calculus vesicæ. It is quite true that the immediate result of irritating the sphincter is to determine in a reflex manner an increase of its contraction, as may be experienced in introducing instruments, &c., into the rectum; but it would also seem that at a certain point the irritation may lead to an arrest of the tonic influence, and so allow the sphincter to yield, and this is particularly the case with affections of the bladder.

b. *From cerebral disease*. That certain emotional conditions may lead to involuntary defecation is well known, and that a similar result follows some diseases of the cerebral centres is not uncommon. The paralysis of the sphincter that occurs under these circumstances is brought about by inhibiting the normal tonic stimulus emanating from the lumbar centres. Involuntary evacuations frequently occur in epileptic fits; in profound comatose states induced by apoplexy, opium and other forms of poisoning; and in death by hanging or suffocation. Its occurrence can scarcely be regarded as indicating lesion of any one part of the cerebral centres, but rather as a result of what at present are termed general brain-states. It constitutes a troublesome complication in such chronic forms of brain-disease as general softening, paralysis of the insane, &c.

γ. *From spinal disease*. The relaxation of the sphincter may of course be produced by disease or injury of the lumbar enlargement of the spinal cord. Inasmuch as it is from the cells of this region that the normal tonic influence is understood to emanate, a destruction of the nervous

them can readily be understood to prevent the origination of such stimulus to contraction. It is noticeable that changes in the substance of the cord itself, myelitis, &c., are more frequently accompanied by paralysis of the sphincter than is spinal meningitis.

3. *From local disease.* The control over the sphincter may be lost from injury to the muscle itself, as occurs in laceration of the perineum, involving the lower end of the bowel.

TREATMENT.—Beyond removal, when possible, of the cause, no direct treatment of incontinence of feces is of avail. As a distressing complication of certain diseases of the nerve-centres, which are too frequently incurable, little remains to be done for it beyond adopting such measures as will permit of the escape of the discharge with every regard to cleanliness. W. H. ALLCHIN.

FÆCES, Retention of.—*Ætiology.*—In the absence of mechanical obstruction, such as adhesions, bands of false membrane, uterine pressure, stricture, tumours, morbid growths or hemorrhoids, the main causes of fecal accumulation are:—(a) a sub-paralysis of the intestinal muscular fibres from defective innervation, or from over-distension of the walls of some portion of the large bowel, (b) loss of reflex irritability of the rectum, and (c) dryness of the mucous surface of the colon. Hence it is frequently met with in the debilitated the bedridden, the paralysed, the aged, and the sedentary, and women are more prone to it than men. Loss of reflex sensibility in the rectum is frequently the sole cause. The feces delivered into the rectum by the contractions of the sigmoid flexure and the descending colon no longer excite the act of defecation, and collecting there as a large desiccated mass, determine a gradual and painless retention in the colon, and particularly in the most distensible parts—the sigmoid flexure and the caecum. The accumulation once set up tends also to perpetuate itself by arresting more and more the peristaltic movements, and leading to atrophy of the walls of the bowels.

Symptoms.—Fæces often accumulate slowly and without the knowledge of the patient, hence in cases in which sensibility has been blunted by age, disease, or great debility, the discovery of large collections in the rectum or colon may surprise even the practitioner, who is generally led to a local examination by disturbances set up by the retention. There is usually constipation or an insufficient discharge of solids, a regular and even excessive relief of the bowels does not, however, exclude accumulation, for even fluid feces may pass through the centre of or over old collections. The evacuations are lumpy, or consist of detached hard, dry, dark scybala, or of a single mass, when the accumulated matters are dislodged by aperients, they often emit an offensive and sour odour. Fæcal collections in the rectum and sigmoid flexure are apt to excite tenesmus and frequent voiding of mucus and blood, but without the putrid flesh-like odour of dysenteric evacuations, and the finger encounters a mass of hardened feces in the rectum.

An accumulation in the caecum, or any part of the colon, may be detected through the abdo-

menal wall as a tumour more or less movable and uneven, and doughy to the touch; and in rare cases the large bowel throughout may be so greatly distended as to apparently fill the abdomen with a solid mass which, like other fecal collections, yields to the firm pressure of the finger. A tympanitic state of the abdomen may, however, so obscure the examination as to prevent the recognition of even moderately large accumulations.

Flatulence, colicky pains, inflammation, (typhlitis, colitis), ulceration and perforation—the caecum is by far the principal seat of this accident—and intestinal obstruction, are not uncommon results of retention of feces, concerning which the reader is referred to the articles on *CONSTIPATION*; *CÆCUM, Diseases of*; *COLON, Diseases of*; *FLATULENCE*; and *COLIC*.

TREATMENT.—A hard ball of feces or of agglutinated scybala in the rectum resisting dislodgment by aperients, or enemata, should be broken up and removed, by introducing within the sphincter two or three fingers, a scoop, or the handle of a spoon. This may be facilitated by introducing the fingers within the vagina in the female. Fæcal concretions in this situation, even though not impacted, may require similar mechanical aid, and in consequence of the hardness and size of these bodies the extraction is frequently difficult. When purgatives and injections fail the former perhaps aggravating the vomiting induced by the obstruction—a long elastic tube should be passed through the indurated mass which resists its progress, and warm olive oil, followed by milk or gruel, should be gradually injected by the stomach-pump or Davidson's syringe, sometimes, however, large injections as ordinarily administered, repeated twice or three times a day, render this proceeding unnecessary. The removal of collections of hard feces in the rectum may be facilitated by ulcerating them with suppositories of cacao-butter, or of glue or isinglass softened in cold water. While a brisk aperient, such as a full dose of calomel, or castor oil with croton oil, may afford timely aid, the general medicinal treatment of the accumulation should consist of a prolonged course of gentle, yet efficient evacuants combined with tonics. The gradual collection of feces, the toneless state of the walls of the large bowel, the scanty secretion of intestinal mucus, and the loss of reflex sensibility in the rectum, require the persevering use of these remedies. A pill containing aloes, belladonna, and nux vomica—to which extract of colchicum is often a useful addition—generally affords the most satisfactory results. When aperients fail to dislodge the fecal collections, and the abdomen becomes painfully distended, a combination of opium, belladonna, and aloes, given at regular intervals—the dose of aloes, at first small, being increased as the pain diminishes—may enable the bowel to overcome the difficulty; but when there is severe pain, and above all obstinate, and especially stercoraceous vomiting, opium and belladonna should be given alone or with nux vomica until the subsidence of these symptoms, when aloes may be prescribed along with these agents with the best effect. Obstruction from paralysis of a portion of

the bowels in which feces have accumulated may be met by strychnia, restoring capacity of action, followed by a mild aperient which promotes peristalsis, or by the interrupted galvanic current. Distressing tympanites, which, thwarting the peristaltic movements, intensifies the obstruction, has been overcome by puncture of the cæcum with a fine trocar or aspirator after failure of other means; but this proceeding is not unattended with danger of fatal peritonitis from fecal extravasation, or from perforative ulceration set up by the punctures, and cannot be safely recommended. GEORGE OLIVER.

FAINTING.—A popular synonym for syncope. See SYNCOPÉ.

FAINTNESS.—Faintness signifies a feeling of great weakness or exhaustion, as if the subject of it were about to become exhausted, or to sink or faint.

FALLING SICKNESS.—A popular synonym for epilepsy. See EPILEPSY.

FALLOPIAN TUBES, Diseases of.—The oviducts are liable to the following morbid conditions:—1. Malformations, 2 Displacements, 3 Contractions, 4 Dilatations, 5 Inflammation, 6, New Growths, and, 7 Tubal Pregnancy.

1. **Malformations.**—The Fallopian tubes may be congenitally wanting, either on one or on both sides; or they may be impervious, and, instead of a single opening into the abdominal cavity, there may be two or more.

2. **Displacements.**—The tubes may be stretched or widely displaced from their normal position by growths or effusions in their neighbourhood, such as ovarian, parovarian, &c.

3. **Contractions.**—These canals may be impervious, from inflammation of the lining membrane, or from peritonitis, pressure, or torsion.

4. **Dilatations.**—The Fallopian tubes may be distended, even to a great degree, by (a) mucous or serous fluid (*hydro-salpinx*), (b) pus (*pyo-salpinx*), or (c) blood (*hæmo-salpinx*). In hydro-salpinx the tubes, if much distended, become sacculated, giving rise to a string of cystic tumours. The fluid collects chiefly at the abdominal end of the tube, but occasionally it may escape, and in large quantity, through the uterus. Should the tube burst and discharge its contents into the peritoneal cavity serious results may ensue, especially if the fluid be pus. When hæmo-salpinx is the result of menstrual retention from atresia uteri, bursting of the tubes internally is apt to follow operations for the relief of the obstruction.

5. **Inflammation.**—Inflammation of the Fallopian tubes (*salpingitis*) is apt to be caused by gonorrhœal infection, or it may occur during the puerperal state. Stenosis or *pyo-salpinx* may be the result.

6. **New Growths.**—The Fallopian tubes may be the seat of the following new growths—fibroid tumours, mucous polypi, cysts, cancer and tubercle, *lipomata*, involving the integrity of the tubes may also arise in the adjacent tissues. Fibroids resemble those of the uterus, and may attain a considerable size. Small polypi growing into the canal may partially obstruct the duct. The cysts are usually the so-called *hydroids* of

Morgagni, an embryological relic; but other small simple cysts may be met with at the orifice of the tube, around the morsus diaboli. Primary cancer of the tubes rarely, if ever, occurs. Tubercle, however, may be primary, and may occur before puberty. It usually begins at the abdominal end, and may lead to blocking of the tube.

7. **Tubal Pregnancy.**—An important affection of the Fallopian tubes is that arising from the variety of extra-uterine pregnancy called tubal, where the product of conception grows within the tube in some part of its course. This abnormality is apt to be attended with very serious results, bursting of the tube frequently occurring about the third month of gestation, and serious, sometimes fatal, internal hæmorrhage may hence ensue. Tubal gestation usually occurs on one side only, while other affections of the tubes are often symmetrical, a point of diagnostic importance. See PREGNANCY, Disorders of.

Regurgitation of blood, of septic matters, and of fluids injected into the uterus, sometimes takes place along the Fallopian tubes, and this accident is always attended by grave consequences.

Mechanical Obstruction of the Fallopian tubes is not an infrequent cause of sterility.

TREATMENT.—The diagnosis of affections of the Fallopian tubes being difficult, their treatment is likewise obscure, and must be in a measure guided by general principles in each case. In pyo-salpinx severe peritonitis and death may result from rupture of the sac, as may speedy dissolution from internal hæmorrhage in tubal gestation. In the former case, and in hydro-salpinx, puncture with the aspirator might be permissible were a clear and unequivocal diagnosis made. In the latter case proximal ligation of the implicated tube might save life, but the diagnosis is surrounded by so many difficulties that such an operation can only rarely be justified.

ALFRED WILTSHIRE.

FALSE MEMBRANE.—An inflammatory exudation of a fibrinous character, which is deposited in layers, chiefly on mucous surfaces, and occasionally on abrasions of the skin. It is well exemplified by the deposit in diphtheria and plastic bronchitis.

FAMILY DISEASES.—Diseases which are found to run in families, or diseases to which members of the same family seem peculiarly liable. See DISEASE, Causes of.

FARADISATION, Uses of. See ELECTRICITY.

FARCY.—A synonym for glanders. See GLANDERS.

FASCIE (fascia, a band).—The fasciæ are subjects of medical and surgical interest, with respect both to their anatomical relations, to the diseases to which they are liable, and to points of diagnosis in connection with them.

1. **Anatomical Relations of Fasciæ.**—The situation and connections of the fasciæ, according as they are fasciæ of *encasement* or fasciæ of *attachment*, are of the greatest practical impor-

cance in the following classes of diseases:—1. Suppuration; 2. Extravasations, and Cellular Emphysema; 3. Herniæ; 4. Dislocations; 5. Diseases of Encapsuled Organs; and, 6. New Growths.

1. **Suppuration.**—The physical influences exerted by fasciæ upon pus are chiefly two. First, fasciæ may limit the size of an abscess, determine its tenacity and the many results of the same, and thus affect both the local phenomena and the general symptoms. Secondly, when the pus is not confined, the fasciæ serve to determine the course that it will take and the situation in which it will discharge. Every abscess may be said to be influenced in this way by the relations of fasciæ, but certain fasciæ have to be specially noted as causing pus to burrow, and hence they should be enumerated here.—

a. Fasciæ of the Head and Neck.—The fasciæ of the scalp, the temporal fasciæ, the cervical fasciæ, and the post-pharyngeal fasciæ, which conducts pus from the cervical vertebrae to the parotid region and tonsil, and to the region of the carotid vessels.

b. Fasciæ of the Upper Extremity.—The axillary fasciæ; and the deep fasciæ of the upper extremity generally, including the palmar fasciæ and the sheaths of the tendons.

c. Fasciæ of the Thorax.—The fasciæ of the intercostal spaces and of the mammary region, the fasciæ reaching from the neck to the upper part of the pericardium and the aorta, and to the posterior mediastinum, respectively, the fasciæ of the anterior mediastinum; and the fasciæ connected with the diaphragm—all of which determine the course of intrathoracic abscesses.

d. Fasciæ of the Abdomen and Pelvis.—The transversalis fasciæ, the fasciæ connected with the transversalis muscle, especially posteriorly, which influence the course of lumbar abscesses, the sheaths of the penis and the iliacs, the pelvic, recto-vesical, obturator and anal fasciæ, the fasciæ investment of the prostate; the superficial and deep layers of the superficial fasciæ of the perineum, the superficial and deep layers of the triangular ligament, and the fasciæ investments of the rectum, bladder, uterus, and vagina, which determine the course of purulent collections in the pelvis.

e. Fasciæ of the Lower Extremity.—The fasciæ lata and its processes, the tensor fasciæ femoris, the popliteal fasciæ, the deep fasciæ of the leg, and the plantar fasciæ and its compartments.

2. **EXTRAVASATIONS AND CELLULAR EMPHYSEMA.**—When blood or urine escapes from its natural reservoir, or when air or gas has found its way an outlet the tissues, the direction that the extravasated substance takes is markedly influenced by the fasciæ with which it comes in contact. The principal fasciæ of importance in this respect are as follows:—

a. Fasciæ of the Head and Neck.—The fasciæ of the scalp, and the cervical fasciæ.

b. Fasciæ of the Thorax.—The fasciæ of the intercostal spaces, and the mediastinal fasciæ, through connections with the cervical.

c. Fasciæ of the Upper Extremity.—The deep fasciæ in general.

d. Fasciæ of the Abdomen and Pelvis.—Scarpa's fasciæ, or deep layer of the superficial fasciæ;

both layers of the superficial and of the deep perineal fasciæ; and the fasciæ of the prostate and bladder—all being of the greatest importance in cases of extravasation of urine or feces.

e. Fasciæ of the Lower Extremity.—The fasciæ lata in general, the popliteal fasciæ; the deep fasciæ of the leg; and the plantar fasciæ.

3. **HERNIÆ.**—The occurrence of herniæ, and the direction that they take, are in a great measure determined by the condition of the fasciæ in contact with the viscera. Most important in this relation may be mentioned—the fasciæ transversalis, the iliac fasciæ, the sheath of the femoral vessels, the obturator fasciæ, the cribiform fasciæ, and the fasciæ lata.

4. **DISLOCATIONS.**—Certain fasciæ serve as supports for the heads of bones, and for the viscera, and these will have an important influence either in promoting or in preventing dislocation, displacement, or other injury of these parts, as the case may be. The shoulder is supported by the costo-coracoid fasciæ, and this relation considerably affects the signs of dislocation at that point. In fractures of the patella, the fasciæ of the knee-joint promote separation of the fragments. The fasciæ of the neck helps to support the pericardium, and must limit the displacements of the heart. The bicipital fasciæ of the forearm protects the brachial artery beneath it in venæ-section, at the bend of the elbow. On the other hand, the attachment of the cervical fasciæ to the jugular veins facilitates the entrance of air into the circulation through a wound at this point. And, lastly, the pelvic viscera are supported by the transversalis, pelvic, iliac, and recto-vesical fasciæ, whilst the cord and testis have their special fasciæ to keep them in position.

5. **DISEASES OF ENCAPSULING ORGANS.**—A considerable number of organs, many important vessels, and a great variety of muscles are contained in distinct fasciæ capsules, sheaths, or envelopes, which will affect the course of the diseases of these structures in many ways—defining their limits, or determining the direction in which they spread, and thus influencing both their local and general phenomena. This has been already alluded to under the first head; but it is necessary to enumerate here the principal fasciæ that act in this way, namely:—*a. Arterial sheaths.*—of the carotid, subclavian, thoracic, aortic, and femoral. *b. Muscular sheaths:*—of the masseter, buccinator, pectoralis, quadratus lumborum, erector spinæ, pectineus, rectus abdominis, levator ani, tensor vaginæ femoris, and the palmar and plantar muscles. *c. Visceral capsules.*—of the thyroid gland, parotid and submaxillary glands, tongue, prostate, penis, vagina, bladder, rectum, and mamma.

6. **NEW GROWTHS.**—The direction, rapidity, and extent of spread of new growths are considerably modified in certain situations by the relations of the fasciæ above described.

II. **Pathological Relations of Fasciæ.**—The principal diseases of fasciæ are:—1. Inflammation and its results; 2. Ossification; 3. Calcification; 4. Rheumatism; 5. Gout; 6. Syphilis; 7. Contraction; and 8. Extension. None of these conditions can be said to be common, or of serious importance.

1. **INFLAMMATION.**—Inflammation involving a fascia is usually secondary, having spread to it from the neighbouring structures, and especially from the muscle or organ of which the fascia may form the sheath. Even under these circumstances, a fascia rather resists than participates in the inflammatory process, as has been described above; and when it is involved it tends to ulcerate on account of its feeble vitality, and to be discharged in the form of sloughs. The healing process is extremely slow in fasciæ, and after serious lesion their function is never completely restored.

2. **OSIFICATION.**—Occasionally in aged persons portions of fasciæ are found transformed into bony tissue.

3. **CALCIFICATION.**—Calcification is very rare in fasciæ.

4. **RHEUMATISM.**—The condition known as muscular rheumatism, or according to its situation as lumbago, torticollis, &c., is believed by some authorities to involve the fibrous coverings or fasciæ of the affected parts. In the same way, many of the aches of some forms of 'chronic rheumatism' may possibly have their seat in fasciæ, and certain cases of neuralgia are probably to be referred to rheumatic inflammation of the nerve-sheath.

5. **GOUT.**—Amongst the pains of the gouty subject are some which are no doubt due to affections of fasciæ, such as pains in the heel and instep, and neuralgia of the sciatic, the anterior crural, and the brachial nerves.

6. **SYPHILIS.**—Syphilis may attack the fasciæ in the form of nodes, which in places of low vascularity are apt to ulcerate, as, for example, at the inner aspect of the knee.

7. **CONTRACTION.**—Contraction is the most obvious of the morbid conditions of fasciæ, giving rise as it does to well-marked deformities. The fasciæ of the hand and foot are most liable to this change, with the result of unnatural flexion of the fingers and toes. Such contraction of the palmar and plantar fasciæ may be due to wounds, burns, or inflammation from any cause, or to gout or rheumatism; it is sometimes congenital, and it sometimes occurs without evident cause.

8. **EXTENSION.**—A fasciæ or sheath, though extremely inelastic, is liable to be stretched by swelling of the parts which it envelopes, and if the cause do not speedily disappear, may remain more or less permanently extended. The best instance of this condition is pendulous abdomen after pregnancy or other form of abdominal enlargement.

J. MITCHELL DUNCAN.

FASCIOLA (*fasciola*, a thin band).—A genus of trematode parasites of which the common liver-fluke forms a good type. This *entozoön* (*Æ. hepaticæ*) is characterised by the possession of a branched intestinal canal, thus differing from the flukes belonging to the genus *Distoma*, in which the canal is simple and bifurcated. The liver-fluke is of rare occurrence in man, though extremely abundant in, and destructive to, ruminating animals. See *DISTOMA*. T. S. CUMBOLE.

FASTING.—The manifestation of vital activity implies consumption of material; and unless the supply of material in the form of

food is equivalent to the loss occurring a progressive wasting of the body and failure of power must ensue. Hence these phenomena constitute the necessary accompaniments of fasting, and with its prolongation the question resolves itself into one of time—when the exhaustion of material shall have proceeded to such an extent as to render the continuance of life impossible.

PATHOLOGY.—To CHOMAT we are indebted for showing that the immediate cause of death from fasting is a reduction of the bodily temperature. At first there is a gradual, but not very extensive fall. Afterwards a more rapid decline occurs, until the reduction amounts to about 29° or 30° (Fahr.) below the normal point, when death ensues. CHOMAT noticed that if, whilst in the state of torpor preceding death, the temperature of the animal experimented on was raised by exposure to artificial warmth, a restoration of consciousness and muscular power was induced, and some of his subjects of experiment which were thus rescued from impending death afterwards thoroughly revived on being supplied with food.

SYMPTOMS.—The most prominent symptoms arising from fasting are those due to the special sensations produced by the absence of food and fluid, and those attributable to a decline of the physical and mental power. In the first place there is great anæmia in the epigastrium. This is followed by a sense of sinking in the same region, accompanied by insatiable thirst, and if fluid be persistently withheld as well as food, the thirst becomes the chief source of distress. The countenance assumes a pale and cadaverous appearance, and a look of wildness is presented about the eyes. Emaciation becomes more and more marked, and with it there is a decline of the bodily strength. There is also failure of the mental power. Stupidity may advance to imbecility, and a state of minimal delirium frequently supervenes. Life terminates either calmly by gradually increasing torpidity, or, it may be, suddenly in a convulsive paroxysm.

DURATION OF LIFE.—The usual duration of life under complete absence of food and drink may be said to be from eight to ten days. The special circumstances, however, existing may exert a modifying influence, and from the nature of these the period may be either diminished or increased. A stout person, as may be readily understood, has a chance of living longer than a thin one, on account of the store of combustible material which may be drawn upon being larger. Exposure to cold in conjunction with starvation very much hastens death. The presence of moisture in the atmosphere favours the prolongation of life, by diminishing the exhalation of fluid from the body. It may be assumed to be owing to the existence of warmth and moisture that persons buried in mines, or otherwise similarly placed, have been known to live considerably beyond the ordinary period.

The Welsh fasting girl, about whom so much excitement was created in 1869, lived exactly eight days from the time she was placed under systematic inspection to solve the problem of whether she could exist, as had been alleged by her parvula, for an indefinite period without food!

It appears that during the first part of the time she was cheerful and exhibited nothing extraordinary. Later on it was found that she could not be kept warm, and ultimately she sank into a state of torpor, from which she could not be roused and which speedily terminated in death.

In the Troedyriw colliery near Pontypridd an inundation occurred in 1877, which led to the imprisonment of four men and a boy in one of the headings of the mine. The accident happened on Wednesday evening, the 11th of April. Efforts were at once made, by means of a cutting, to reach the chamber in which the imprisoned persons were confined, and to release them. This was not accomplished till the afternoon of Thursday, the 19th, when all were rescued alive and did well. They had been imprisoned in an atmosphere of compressed air nearly eight days, without food but within reach of water. The more recent case of Dr. Tanner throws no new light upon the subject.

THE FAST.—Caution is required in the administration of food after prolonged fasting. Sudden transitions of all kinds are trying to the body; and, instead of allowing the rescued sufferer to gratify his desire to eat and drink according to his inclination after several days' abstinence, the supply of both food and drink should at first be limited and afterwards gradually increased. There is reason to believe that the non-observance of this rule has upon some occasions been followed by disastrous consequences which a different plan might have averted.

F. W. PARRY.

FAT.—Fat becomes a disease under the following circumstances:—

1. As **Obesity**.—Fat may be found generally diffused in excessive quantity beneath the skin, beneath serous membranes, and in and upon the various tissues and organs of the body. This condition constitutes what is known as **Obesity**. The subject will be found fully discussed under that head.

As a **Partial Growth** of fat, which sometimes occurs in paralysed muscles, and constitutes a characteristic feature of what is called **pseudo-muscular hypertrophy**. See **PARALYTIC PSEUDO-MUSCULAR HYPERTROPHY**.

2. As **Fatty Interstitial Growths**. Fat as fat-tissue becomes more especially a disease when it is deposited upon and in the texture of organs, interfering with their structure and functions. It does this by pressing upon the elements of the organ invaded, and its effects are more particularly seen when it invades the muscular tissue of such an organ as the heart, the fibres of which, becoming more or less atrophied and distorted in their course and direction are rendered inadequate for the performance of their functions. See **HEART, Fatty Diseases of**.

3. As **Fatty Tumours**.—Fat may also occur in isolated or circumscribed masses, constituting what are known as **Fatty Tumours** or **Lipomata**. See **TUMOURS**.

4. As **Fatty Infiltration**.—Fat in the form of oily particles is found to be present in excess in the cells of various secreting organs, constituting fatty infiltration. Thus it appears in the epithelium of the intestinal mucous membrane

during digestion; in the cells of the liver and biliary passages; and in the kidneys of certain animals—for instance, the cat. When this condition becomes permanent it must be considered as a disease. Glandular organs thus affected, as in the case of the liver, assume a buff or yellow colour, and become softer and more friable than normal; while microscopically their cells are found to contain one or more large well-defined oil globules, which tend to coalesce and occupy the cell. The quantity of oily matter in the cells may, however, vary from time to time, and the infiltration may be either of a transient or of a permanent character. In the one case, the function of the organ may not be materially interfered with; in the other case, the activity of the cells may be so far affected as greatly to impair the secreting functions of the organ.

The causes of fatty infiltration are of two kinds—general and local. First, the **general** causes are (1) a superabundance of fatty matters in the blood, as occurs in persons who indulge in rich food and in beverages containing alcohol; (2) imperfect oxidation, as in chronic tuberculosis of the lungs, and (3), according to some observers, the metamorphosis of fatty deposits from one part of the body to another.

Secondly, with respect to the **local** causes of fatty infiltration, one is a peculiar affinity or selective power of the cells of certain tissues, by virtue of which they incorporate with their substance oily or fatty matter. This facility has been explained in the case of the cells of the liver and of the passages traversed by bile, by the presence of that fluid, which, as Virchow and others describe, is a powerfully determining cause of the infiltration of fat into protoplasm. Another local cause of the accumulation of oil in cells is their inactivity or imperfect power of eliminating it, as is found to occur in the cartilages of the aged, and in inactive muscles.

It must be said here, with respect to the appearance of fat in the last-named situations that though, in some cases, it is derived unquestionably from the fat contained in the blood or chyle, it may in other instances be derived from the disintegration of the protein elements of the tissues. This subject, however, will be found discussed in the article upon **FATTY DEGENERATION**. R. QUAIN, M.D.

FATIGUE (*fatigo*, I weary).

GENERAL REMARKS.—Fatigue is a regular and constantly returning symptom experienced by all persons. Periods of functional activity invariably alternate with periods of repose during which the whole caused by the exercise of function is repaired. We are indebted to Sir James Paget for having pointed out that 'rhythmic nutrition is a law of nature,' and although the truth of this dogma is recognised on all hands, and may be said to be axiomatic, it has hardly received that careful consideration at the hands of practical physicians which it deserves. Our whole life is composed of a series of vibrations—periods of tension alternating with periods of relaxation; and although the rapidity of these vibrations varies immensely, they are recognisable in all our acts, whether voluntary or otherwise. The vibrations of the heart are about seventy in a

minute, those of the respiratory organs about sixteen. The whole body requires a certain period of absolute and continuous repose in each twenty-four hours (amounting to nearly one-third of the period), so that we may say its rate of vibration is once in the twenty-four hours. In like manner the period of relaxation of the heart is about one-third of the total period of a revolution, and this proportional correspondence between a local and a general condition is not a little interesting and suggestive. Again it is universally ordained amongst civilized nations that once in every seven days there shall be a remission of labour and a change of occupation, and we recognise the fact that it is highly advisable for those who are occupied in one pursuit to break away from it at least once a year and indulge in that variety of work which we call amusement.

Fatigue occurs directly we attempt to alter the rhythm of our vital vibrations by prolonging the periods of tension at the expense of the period of relaxation, or by demanding for any length of time a quickening of the normal rate of vibration. We recognise the fact that athletes who over-train run risks of cardiac troubles and loss of wind, that the man who from any cause is unable to sleep runs a serious risk of permanent impairment of health, and when we find patients pursuing their avocations too zealously we know that, if such offence against the laws of nature be persisted in, general paralysis, or other forms of 'break-down,' are likely to be the result.

Fatigue may be *general* or *local*, and both forms may be either *acute* or *chronic*. That fatigue in all its forms is due to impaired nutrition there can be little doubt, and we shall find that the symptoms of chronic fatigue are often the prelude of definite and recognisable degenerative changes.

DESCRIPTION.—General Fatigue.—General fatigue is recognised with ease both in its acute and chronic forms. There is a disability to perform either mental or physical work, and this disability is noticed first in work requiring attention or sustained effort, and last in those acts which have become automatic or secondarily automatic. The symptoms of general fatigue are usually referable to the nervous centres.

Local Fatigue.—Local fatigue is either acute or chronic, and the symptoms of it are referable usually to the muscles, but we must always bear in mind that muscle and motor-nerve are practically one and indivisible, and that recent experiments have given great probability to the idea that every muscle is connected with a certain definite spot in the brain. When, therefore, we speak of a sense of fatigue, we must necessarily be in doubt, notwithstanding the fact that the symptoms are apparently located in the muscles, whether the brain, nerve, or muscle, one or all of them, be really at fault.

Acute local fatigue.—The symptoms of acute local fatigue are, first, loss of power to a greater or less extent. By too frequent or too prolonged stimulation the irritability of the muscular tissue becomes exhausted, and it either refuses to respond, or responds but feebly to the stimulus of the will; whilst our power of adjusting the force of contraction to the act to be accom-

plished is lessened, and accuracy of movement and delicacy of co-ordination are destroyed. The second symptom of acute fatigue is tremor, as everyone must have experienced who has been called upon for any unusual exertion. The third symptom is cramp-like contraction; and the fourth is pain, the pain being the pain of fatigue and absolutely distinct from other varieties of pain. Fatigue is caused far *more* by prolonged muscular effort than by repetitions of short muscular efforts having due intervals of relaxation between them. Anyone who has attempted to hold out a weight at arm's length knows the impossibility of continuing the effort for any length of time, and it is proverbially true that standing in one position is, to most people, far more tiring than walking, the reason being that in standing the muscles which support the body are subjected to a prolonged strain while in walking we use the muscles on either side of the body alternately. The great increase of power which we obtain by using the muscles on either side of the body alternatively would seem to be one of the chief reasons for the bilateral symmetry of the body. Not only is sustained effort a far more potent cause of fatigue than repeated effort, but we find that when fatigue supervenes, actions requiring sustained effort are the first to fail and in this local fatigue resembles general fatigue. The last acts to be affected by fatigue are such as are automatic, and are accomplished without mental effort, and by the expenditure of the least possible amount of force. It is quite possible to exhaust a muscle by artificial stimulation, and if one of the small interosseal muscles be continuously stimulated, it will be found that in a very short time its power of contraction to any form of stimulus may be absolutely abolished. It is tolerably certain that the brain can have no share in artificial fatigue thus produced, and there seems good reason to suppose that, in some people of energetic temperament, the irritability of a muscle may be exhausted, while the power of mental stimulation remains almost unimpaired.

Chronic local fatigue.—This form of fatigue has causes and symptoms similar to those of acute local fatigue, and there can be little doubt that this condition is a common cause of many of those chronic maladies which seem to result from overwork, and are characterised by irregular muscular action. That some cases of writer's cramp (see WRITER'S CRAMP) are due to chronic fatigue of certain muscles employed in writing, and particularly of those subjected to prolonged effort, there can be little doubt. Some cases of torticollis seem due to the same cause. Duchenne and Brudenell-Carter have pointed out how, in cases of 'short night,' the strain on the internal recti has caused troubles of vision, and even brain-symptoms, and quite lately Mr. C. B. Taylor, of Nottingham, has shown reason for including in the category of fatigue-diseases a peculiar form of nystagmus, occurring amongst miners, who try their eyes by working in the dark.

TREATMENT.—The treatment of fatigue in all its forms is *rest*, and the restoration of the proper rhythm of nutrition, if this be found perverted, by substituting rhythmical exercises for un-rhythmical efforts. G. V. POONA.

FATTY DEGENERATION.—*SYNOPSIS.*—Fr. *Hydropneumose graisseuse*, Ger. *Fettige Metamorphose*.

DEFINITION.—The process by which protein elements are converted into a granular fatty matter.

SEATS OF OCCURRENCE.—This change may occur in any of the component elements of the body, whether normal or abnormal.

Physiologically. The production of milk from the protoplasm of the mammary cells, and of sebum from the cells of the sebaceous glands, are instances of fatty degeneration. The cells of the corpus luteum are partly in a condition of fatty degeneration, and it is by a similar change in the peripheral cells of the mature fetal portion of the placenta that normal involution of that organ is accomplished. Non-vascular structures, such as the cartilages, the cornea, and the intima of blood-vessels, frequently undergo fatty transformation of part of their substance. In a less marked form, fatty degeneration occurs in the walls of the uterus and other muscular organs when returning to their ordinary size after temporary hypertrophy.

Pathologically. As a purely morbid process, fatty change is most frequently met with in the muscular tissue of the heart, in the walls of capillaries, and in the urinary tubules, but it also occurs in the central nervous system, constituting the condition known as 'white softening', in the liver; and in tubercular deposits, cancerous growths, infarcts, and inflammatory products in any situation whatever.

ANATOMICAL CHARACTERS.—*Physical Characters.*—An organ that has undergone fatty degeneration presents the following physical characters. The bulk and weight are generally increased; the consistence is reduced, sometimes to a pulp, as in white softening of the brain, the colour is changed, either as a whole or in the affected portions of the organ, into a buff or yellowish bloodless hue, and the resistance or firmness is diminished, so that the affected tissue is markedly flabby, and readily yields to pressure. The solid cut surface may appear compact and shining; and the section leaves a greasy stain upon the knife and fingers. When fatty degeneration is greatly advanced, as it may be seen, for example, in the liver, a portion of the organ thrown into water will float.

Microscopical Characters.—In fatty degeneration the muscular tissue of the heart and the walls of capillaries are most suitable for microscopical investigation. The earliest changes in the cardiac muscle in fatty degeneration are loss of sharpness of the individual striæ and the appearance of minute particles of oil between the elements. These changes, beginning near the nuclei, spread throughout the fibres in a longitudinal direction, while the particles increase in size and assume the well-known characters of oil-globules. When the process is advanced, the whole of the sarcolemmal substance is replaced by fatty particles contained within a delicate albuminous envelope. Finally the degenerated fibres either become atrophied by absorption of certain parts of the fat, and so disappear, or suffer rupture with discharge of their contents. The fatty nature of the change is proved by the solubility in ether of the particles that have escaped from the fibres.

Fatty degeneration of the walls of veins, is best seen in the capillaries and smallest arteries. The tunics first lose their normal transparency; minute granules appear in their substance; and these increase to form unmistakable oil-globules. Finally the vessel gives way, and the oily particles and blood are discharged into the perivascular space.

In the other organs referred to, the microscopical characters agree with those just described, with certain differences dependent upon the special structure of each. Thus fatty degeneration of a leucocyte leads to the formation of the body known as a *compound granular corpuscle*, in which the oil-drops finally replace the whole of the protoplasm. In 'white softening' of nervous tissue, the nerve-cells and probably all the nuclei of the part are converted in a great measure into granular corpuscles; and these breaking down into a fatty detritus, the whole constitutes a soft creamy-looking substance, which, as Virchow expresses it, 'is milk in the brain, instead of in the mammary gland.' 'Yellow tubercle' consists in part of cells and nuclei that have undergone fatty degeneration, and of fatty detritus. In the case of the uterus during involution the fat is probably rapidly absorbed, so that the appearances presented to the eye are those rather of atrophy than of replacement of the muscular substance by fat.

PATHOLOGY.—We have now to trace whence comes the fat that is found in this form of degeneration, and how. It is evident that in a number of instances—such as the production of milk and sebum—fatty degeneration is a truly physiological change, which is subservient to health when active, while its derangement or cessation constitutes disease. In other cases the process is essentially pathological, as, for example, in fatty degeneration of the heart and white softening of the brain, the functional activity of the part being impaired, or so abolished that the name of *macrobiosis*, or death-in-life, has been given to the condition. The fatty change in the two instances is, however, manifestly one and the same. The condition known as fatty degeneration had long been described, and it has always been a favourite subject with pathologists to discover its nature and its cause. It was generally assumed that the fatty matter present was introduced from without, being deposited from the blood as morbid material in place of the pre-existing tissues which were absorbed. Modern research has demonstrated that this is not so, and that fat is derived from a molecular change in the tissue or textures in which it is found. The subject is one of immense importance, involving the whole field of pathology; and it is but right to state that our acquaintance with the true nature of the process, is almost entirely due to the investigations of Dr. Quain, which were published in the *Medico-Chirurgical Transactions* for 1850, and with reference to which Sir James Paget has remarked:—'Dr. Quain has candidly referred to many previous observers by whom similar changes were recognised; but the honour of the full proof, and of the right use of it, belongs to himself alone.'—*Lectures on Surgical Pathology*, 1st ed. vol. i. p. 107, note. Dr. Quain's conclusion was that the molecular fatty

matter in the degenerated fibre was the result of a chemical or physical change in the composition of the tissue, occurring independently of those processes which we call vital. The arguments which he adduced in support of this view were the following:—(1) That in the formation of the substance known as adipocere from albuminous material after death, the places of the muscular fibres, blood-vessels, and nerves are occupied by fatty matter which could not have existed in them as such during life. (2) That a true fatty degeneration may be artificially produced *post mortem*. (3) That masses of albuminous material deprived of nutrition in any part of the body, or the centre of non-vascular structures such as tubercle, undergo fatty degeneration to a marked degree. (4) That the circumstances under which fatty degeneration occurs in the living body exhibit impairment of general and local nutrition, such as blood-disease, or disease of the nutrient vessels. More than twenty years later (1871), Dr. Quain's conclusions respecting the nature of fatty degeneration were experimentally confirmed in the living animal by the investigations of Bauer and Voit, of Munich. On administering phosphorus to a starving dog, in which the amount of nitrogen (urea) daily excreted had become constant, these experimenters found that the amount of the excretion was thereby increased threefold; that this nitrogen was derived from the albumen of the tissues and not of the blood, and at the same time that three times the normal amount of oil had accumulated in the viscera. This oil could have its origin only in the transformed or decomposed albumen of the organism; the other product being the urea which had been excreted. The same results have been observed in poisoning by phosphorus in the human body.

Many other instances of the formation of a fatty from a nitrogenous body might be adduced if necessary, such as the ripening of cheese, the increased flow of milk on a meat diet, the formation of wax by bees from sugar and albumen, the production of fatty acids and their allies from proteid compounds in the process of pancreatic digestion; the increase of oil in olives by keeping; and the development of a rancid oil in the fluke of salmon under similar circumstances. The numerous instances just adduced combine to strengthen the position—which was, however, sufficiently established by Dr. Quain—that in true fatty degeneration, the nitrogenous material of the tissues themselves, and not the blood, must be considered the source of the oily matter. It has been said that the circumstances under which fatty degeneration occurs are further confirmatory evidence in the same direction. These must now be considered.

CONDITIONS OF OCCURRENCE.—The circumstances under which fatty degeneration occurs are either such as affect the nutrition of the whole system generally, or of a given organ, or portion of it, specially.

General.—When the amount of blood in the body is quickly reduced, for example, by severe but not actually sudden hemorrhage, death may occur from fatty degeneration of the heart, the voluntary muscles and the other viscera being likewise, but less seriously, affected. Again,

general fatty degeneration is frequently due to depraved quality of blood, and especially to the presence in it of certain poisons, such as phosphorus, arsenic, antimony, and the more complex animal-poisons of the acute specific fevers.

Local. Disease of the nutrient artery of a part is the morbid condition most frequently associated with localised fatty degeneration. A good instance of this is furnished by fatty degeneration of patches of the muscular tissue of the heart corresponding with degeneration, obstruction, or compression of a branch of a coronary artery. Another excellent example of the same is white softening of the brain from vascular degeneration. This is analogous to what occurs in dry gangrene, with the exception that decomposition takes place in the latter, probably from the admission of air.

SUMMARY.—When we review the circumstances under which fatty degeneration is found to occur, we discover that the condition that is common to them all is interference with nutrition, and especially with the process of oxidation. The red corpuscles are believed to be primarily affected in phosphorus-poisoning; they are numerically reduced in continued hemorrhage; and they do not reach the tissues in sufficient numbers when the vessels are obstructed, or otherwise diseased. In the cases of the hypertrophied uterus and heart, of the placenta, and probably of the corpus luteum, the degeneration is probably due to the decline or cessation of functional activity, and the consequent decrease in the blood-supply to the large mass of protoplasmic structures.

With respect to the *intimate or essential nature* of fatty degeneration, it may be stated as highly probable, as far as our present knowledge extends, that the metabolism or decomposition that is constantly going on in living protoplasm is not simple or immediate; but that a primary decomposition occurs of albuminous substances into urea (or its allies) and fat, and a further or secondary decomposition of the fat into carbonic acid and water. If the amount of oxygen furnished by the blood is deficient, whether absolutely or relatively, the primary decomposition of the protoplasm alone may be effected; and the secondary decomposition, or the oxidation of fat into carbonic acid and water, may not occur. The result therefore of an absolute or relative deficiency of oxygen in protoplasmic tissues will be the accumulation of fat within them.

EFFECTS.—The physical effects of fatty degeneration of a tissue have been already described under the head of physical characters, being chiefly—change of colour, diminished consistence and resisting power, softening, rupture, dilatation and excavation, and alteration of size. The chief physiological effect is diminished functional power or activity, which is especially marked in muscular parts such as the heart, and in the kidneys.

TREATMENT.—The subject of the treatment of fatty degeneration will be found discussed under the head of the diseases of the several organs which it may affect. J. MITCHELL BRUCE.

FATUITY (*fatuus, silly*).—Mental imbecility. See IMBECILITY.

FAUCES, Diseases of. See THROAT, Diseases of.

FAVUS (*favus*, a honey-comb).—**SYNON.**: *Fava faecosa*; Fr. *Favus*; Ger. *Wachsgirnd*.

ÆTIOLOGY.—Favus is very uncommon in England, it is more frequently seen in Scotland and abroad. It usually attacks the scalp, rarely the body, of young children amongst the poorer members of the community. It may be contracted from certain animals, especially mice.

ANATOMICAL CHARACTERS.—If the favi be examined microscopically—that is, if small portions be placed in potash and put under the microscope—they are seen to be made up entirely of fungus. The fungus by its growth irritates the scalp, and making its way down the hair-follicles, it finds access to the hair-shafts which are swollen, altered in texture, and loaded with fungus-elements, whilst the hair-forming apparatus becomes more or less destroyed and the hair falls. The fungus (*achorian Schenckii*) consists of oval, nucleated conidia, $\frac{1}{100}$ inch in diameter, free, jointed or constricted, large branching or tortuous mycelial filaments, $\frac{1}{100}$ inch or so in diameter, filled with granules and spores, and stroma made up of minute cellular elements.

DESCRIPTION.—The characteristic feature of the disease is the development of light sulphur-coloured circular, cupped crusts, called *favi*, penetrated by the hairs in their centres. At first a minute opaque spot is visible beneath the epidermis, and this gradually enlarges into a *favus*. These favi are about the size of a split-pea, or larger, varying, in fact, from $\frac{1}{8}$ to $\frac{3}{4}$ of an inch in diameter, and $\frac{1}{16}$ to $\frac{1}{2}$ of an inch in depth. They lie or are imbedded in a depression of the derma, and are convex therefore on their under aspect, but concave above, and the surface has a stratified appearance. These favi may be discrete or crowd together into an irregular mass, in which the distinctness of the several favi is more or less lost. In severe cases redness, soreness, tumefaction of the scalp, and baldness result.

DIAGNOSIS.—Favus may be mistaken for impetigo at first sight, but only by a careless observer, because characteristic favi are always present.

TREATMENT.—The treatment is both disappointing and tedious. The patient must be placed under the best hygienic regime; his nutrition must be improved by good living, and the exhibition of cod-liver oil, steel, and quinine; the favi must be removed by poulticing, and parasiticides must be continuously applied, in conjunction with the practice of epilation. At first sulphurous acid lotion (one part to three or four of water) may be continuously soaked-in for some time; and this may be followed by the friction of iodide of sulphur ointment, double strength, if it can be borne, to which is added oil of eucaly in the proportion of two drachms of the latter to an ounce of the former.

TILBURY FOX.

FEBRICULA (*febricula*, slight fever).—**SYNON.**: Fr. *Febricule*, Ger. *Febricula*.

DESCRIPTION.—Simple fever, of one (*Ephemera*) or not more than a few days' duration; not preceded by any known invariable antecedent; and not attended by any one definite organic lesion.

It may well be doubted, however, whether such a thing as simple fever, in the strict sense of the term, exists; anyhow it must be one of the rarer forms of disease. The conditions which, from our necessarily imperfect knowledge, it is convenient to call *Febricula* are numerous and of great practical importance. They may be somewhat roughly grouped as follows:—

1. Abortive or incomplete forms of some one or other of the specific continued fevers, namely, typhus, typhoid, or relapsing. The writer's own experience leaves no doubt in his mind that such irregular forms are met with during epidemics of those diseases.

2. Instances of some of the exanthemata, especially scarlatina and modified variola, in which the usual rash is either absent or so slight or brief as to pass unnoticed.

3. Intermittent fevers in which for some reason or other the paroxysms do not recur, or only at uncertain and distant intervals.

4. Cases in which the local symptoms usually attending certain forms of fever are very slight or very obscure, and therefore difficult, perhaps impossible, to detect. Instances of this occur in connection with tonsillitis, erysipelas, rheumatic fever, and tubercular disease.

5. Cases in which considerable febrile movement is present during the development of the primary as well as of the secondary symptoms of syphilis, and of which it is not easy to ascertain the real cause.

6. Fever as the consequence of exposure to a high external temperature, for instance, the *febris ardens* of tropical climates (Murchison); and of violent and prolonged muscular exertion.

7. Fever as the consequence of irritation of any organ or tissue, such as the stomach by indigestible matter, of the colon by scybala; or of catarrh of a mucous surface, for example, urethral fever.

8. Certain ill-understood but not uncommon disorders of nervous centres, cerebral, spinal, or sympathetic, are often followed by febrile movement.

ANATOMICAL CHARACTERS.—Fever, however caused, which runs high produces congestions and tissue-changes in the viscera, especially in the lungs, but, in view of the short duration of febricula, it would in most cases be impossible to decide whether any pathological changes found after death were the consequence or the cause of the febrile movement. It is possible, but not yet proved, that there may exist some contagion capable of producing febricula, and febricula only.

SYMPTOMS.—Febricula is characterised by a rise of temperature, rarely exceeding 102° F., but sometimes, especially in cases due to exposure, reaching 105° F. or even higher, although only for a short time. The access of fever may be gradual, or marked by slight rigors, and some or all of the common clinical symptoms of fever may be present in varying proportion and in greater or less degree, such as general malaise; dry skin; frequent pulse, amounting to 100 or 120 per minute; tongue furred and with a more or less distinct central dry reddish-brown streak; thirst, loss of appetite, and nausea; constipation, scanty high-coloured urine;

and headache, intolerance of light, slight deafness, restlessness, sleeplessness, and slight delirium at night.

DIAGNOSIS.—The diagnosis of febricula rests upon the exclusion of all the other recognised kinds of idiopathic or of symptomatic fever. As a matter of practical diagnosis at the bedside, almost every disease attended by rise of temperature is now and then, at its outset, mistaken for febricula.

PROGNOSIS.—The prognosis depends upon the degree and duration of the pyrexia, but in this country is almost always favourable.

TREATMENT.—In the absence of any special indication, rest in bed for a day or two, liquid food until the desire for solids returns, and, if constipation be a marked feature of the case, a moderate dose of some mild purgative, will be sufficient. It is, however, always prudent to remember that what seems to be febricula may be the beginning of some serious and perhaps highly infectious disease. Cooling drinks such as Citrate of Potash in effervescence, Liquor Ammonie Acetatis with a little Spirit of Ether, or Nitro-hydrochloric or Dilute Nitric Acid (one drachm to a pint of water) with some fresh lemon-juice added, may be given according as the one or the other is grateful to the patient. Anything like active treatment, except the use of the cold or tepid bath in cases of heat-fever, is unnecessary, rarely does good, and is almost always positively injurious. J. ANDREW.

FEBRIFUGES (*febris* a fever, and *fugo*, I drive away). **SYNON:** Antipyretics.

DEFINITION.—External applications or internal remedies which tend to lower the bodily temperature when it has been abnormally raised by the processes of fever.

ENUMERATION.—The principal febrifuges, given in the order of their activity, are: Cold Baths, Cold Affusion or Wet Pack, Alcohol, and Diaphoretics; Salicylic Acid, Quinine, Digitalis, and Aconite; Trimethylamine, Iron, and Water and Diluents generally.

ACTION.—Following Professor Hinz, we may divide febrifuges into two classes—1. those which directly withdraw heat from the febrile organism; and, 2. those which lessen its production.

1. In the first division we must give the foremost place to cold baths, which powerfully abstract caloric from the surface of the body and rapidly cool down the blood. Diaphoretics and alcohol act more feebly in the same direction, by dilating the cutaneous arterioles, and thus allowing the mass of the circulating fluid to be effectually exposed to the chilling influence of the air. See **COLD**, Therapeutics of; and **DIAPHORETICS**.

2. Secondly, we have to consider those drugs which actually check the febrile condition itself, and our explanation of their effects must naturally depend on the views held regarding the intimate nature of fever. If we believe in an over-lame or paralysed condition of the nervous system as any essential factor, or if we look upon the vascular structures as primarily at fault, then we must shape our theories accordingly; but if we believe, with our best authorities, that the true explanation must be looked for in the introduc-

tion of extraneous ferments or septic material into the blood, the matter is much simplified. Quinine and salicylic acid then merely act in virtue of their antiseptic power over protoplasm, and if malaria really depends on the fermenting influence of vegetable germs from decaying vegetation, then the so-called specific action of quinine is readily explained. Again, temperature may be lowered by checking the oxidation of the tissues, and interfering with the oxygenating function of the hemoglobin, and alcohol is said more particularly to act by lessening the activity of secreting cells. The free use of water tends to promote excretion, and thus to remove the products of oxidation.

USAGE.—Antipyretic treatment is not adopted in this country as a matter of routine, holding as we do that temperatures raised within certain limits are not *per se* elements of danger, and that even although we may effectually cool down our patient, the progress of the disease may go on quite unchecked. But when the thermometer registers 105°, and still tends upwards, we know that dangerous limits are reached, and that as a rule life is not long sustained after 107°. It then becomes our duty to interfere, and this is best done by plunging our patient into a bath at 95°, and gradually cooling it down to 65°. When the temperature goes down to within 4° or 5° of the normal we remove him to bed, remembering the dilatation of vessels which must follow the contracting effect of cold, and the consequent cooling process which must continue to go on. Here as in all febrile conditions, the thermometer is our surest guide, and we must be directed by it as to when to resume the treatment, for frequent repetition may be needed, and on the Continent as many as 200 baths have been given in the course of a single illness. Along with this the Germans combine the use of large doses of quinine; but notwithstanding the marked tolerance of the drug under pyrexial conditions the danger of perilous depression from such free medication is no imaginary one, and, putting aside apart, we find this valuable drug most beneficial in such fevers as seem to owe their origin to septic poisoning. Digitalis is not a powerful antipyretic, and in large doses is too depressing to the heart, and too apt to produce gastric derangement, to inspire much confidence, while veratrum seems simply to act by throwing the patient into a form of collapse. The influence of salicylic acid over acute rheumatism is remarkable, as it seldom fails to reduce temperature and relieve pain in forty-eight hours, but in other febrile conditions its beneficial action is by no means so well marked. Iron is of value in erysipelas, and exerts some controlling power over acute rheumatism. Aconite and diaphoretics are of un doubted service in aiding the deferescence of some of the minor febrile disorders. R. FARQUHARSON.

FEBRIS (Latin). See **FEVER**.

FEIGNED DISEASES.—No insignificant part of the real difficulty in the practice of our profession depends on what we may call feigned diseases. The art of diagnosis consists in the power of recognising morbid conditions with skill and promptitude; and in proportion to the natural sharpness and well-digested experience

of the medical man, is his success in the discrimination of one symptom from another which resembles it more or less superficially. Many disorders possess a strong family likeness in their very early stages, whilst others may prove deceptive throughout their whole career, and if to this we add the efforts at deception occasionally resorted to by impostors, we see the caution which must of necessity be adopted by those who exercise their calling within wide limits. In considering, therefore, the subject of Feigned Diseases a greater amount of order may attend our studies if we adopt the following simple classification—

1. Those diseases which naturally resemble one another, and in the deception attending the diagnosis of which the patient has no share.

2. Those diseases which are also difficult of diagnosis, but in which the patient involuntarily deceives under some morbid nervous impulse.

3. Cases in which the patient acts himself deliberately and elaborately to deceive those around him.

1. Under this heading we may perhaps include the exanthemata and other acute febrile affections, which are confessedly difficult of diagnosis before the eruption or other marked points of difference are fully established. Important though it may be, in the case of public schools or large bodies of men, to act promptly in the face of such an emergency, the medical man will often feel himself compelled to postpone his decision, but he should at the same time act on the defensive by the timely exercise of quarantine and hygienic precautions. Some diseases, again, are difficult to distinguish from one another, even after their prodromata have passed away, and among these we may include small-pox and pustular syphilis, which occasionally in our own experience have caused more than a shade of suspicion to pass over the mind, whilst mild variola and severe varicella must always have too many points in common, to render them otherwise than stumbling-blocks even to the initiated. Various forms of roseola may closely simulate measles, scabies is often hardly to be picked out from amongst the eruptions which its irritation causes, whilst throat-affections may apparently overlap each other and engender the idea of diphtheria when nothing more than superficial or aphthous ulceration really exists. But it is when the ailment under which our patient labours resembles something else during its whole career, that mistakes are naturally most likely to arise. We are frequently shocked with more scandal in which the innocent victim of brain- or other organic disease has been consigned to a police-cell, and where the plea of drunkenness has been attempted to be sustained by the guardians of the public peace. So difficult is it to make a really trustworthy diagnosis between the coma of alcohol, of uremia, of opium, and of certain apoplectic conditions, that the really cautious and well-informed practitioner would prefer not to attempt to do so often. It is impossible to lay down any general rules, but we may remember that alcohol in poisonous doses lowers the temperature and dilates the pupil; that in uremia an examination of the urine will put us in the right track, whereas opium will produce a con-

tracted pupil, and in cerebral hemorrhage some elevation of the body-heat may not improbably be observed.

But all these points may fail us from time to time, and we had best act at all times as though the case were really a serious one, and worthy of being treated by all the best resources of the medical art.

A very little consideration will enable every experienced practitioner to recall other instances of this sort of natural mimicry, of the difficulty he must often experience in deciding between syphilitic and other brain-affections, of the close affinity between pulmonary consumption and dilatation of the bronchial tubes; of the resemblance between specific and malignant ulcerations; between various diseases of the testicle, the bladder, and the stomach, respectively. All these form part of the regular teaching of medicine and surgery, and will be treated of at greater or less length elsewhere.

2. We must now consider the cases in which diseases are feigned not by the direct action of the patient himself, but because he is unable to resist the vagaries of his weak and excitable nervous system.

Problems of the greatest complexity and difficulty are here presented to the medical man and require for their due solution much tact and experience. Functional affections so closely simulate organic disease under these circumstances that suspicion is often completely disarmed, and treatment adopted the very opposite of that which would most probably prove curative. Hysteria in its protean forms, supplies the greater number of these cases, and may very closely simulate a large variety, more especially of neurotic conditions. Paraplegia, incontinence of urine, joint-affections—in short, almost any disease which does not admit of palpable objective demonstration—may thus be feigned, and very severe treatment may even be adopted under the belief that real organic changes have to be met by the usually appropriate remedies. It is only necessary for us to refer thus briefly to these perplexing cases here, but it must always remain an interesting problem as to how the mechanism of causation here works, so to speak, and whether the patient actually suffers the acute pain of which she complains so forcibly. Sympathy, as we well know, however, is quite thrown away when dealing with these persons, and apparent roughness, with nerving tonics, and mental discipline, will often effect a cure, when the most elaborate combinations of other drugs ignominiously fail. A sudden shock, the pressure of poverty, or the absolute necessity for immediate exertion, will often effectually and permanently arouse the bedridden hypochondriac of many years, and restore him to his friends as a useful member of society, and we need never despair of success even under apparently hopeless circumstances. And although in minor measures the hypochondriac may fancy that every organ in succession is the seat of disease and may even succeed in thus imposing on the unwary, the experienced practitioner will speedily detect the fiction and be able to relieve the unhappy sufferer from the weight of his woes.

But let it not be forgotten that 'expectant

attention, or the constant direction of the mind to the supposed morbid condition of any particular organ, may actually catch the unconscious deceiver in his own net by converting mere functional disturbance into organic disease.

2. To the third division of our subject the term *Feigned Diseases* can perhaps alone strictly be applied. Here we are met face to face with deliberate and premeditated imposture, and there is nothing for it but to match our own wits against those of the deceiver, and to thwart his native cunning by the superior sharpness of science. Now, there is nothing in the history of medicine more remarkable than the elaborate expedients adopted, and the amount of actual discomfort and suffering endured, by persons who have been desirous of escaping military or other duty. The exhaustive works of Gavin and Marshall, and Bonneau and others, give us details no less ingenious than interesting of these devices, but it is curious to note in how limited a range the more traditional modes of imposture seem to run, and how the same old stories are made to do duty over and over again. Thus we read of blindness, and deafness, and epilepsy, and paralysis being carefully imitated, and can hardly withhold our admiration from the astonishing tenacity with which the apparent symptoms were duly maintained. Incontinence of urine, dysentery, hæmoptysis, jaundice, and insanity were among the most favourite rôles in the repertoire, and ingenious as were the preparations for duly sustaining the part, no less ingenious were the means for detection, which usually proved successful. However carefully the impostor had studied his character, some little point was usually omitted. The yellow conjunctiva of jaundice can hardly be feigned, the incontinence of urine was generally found to be attended by an expulsive effort, the blood apparently proceeding from the lungs was by no means intimately mixed with the pulmonary mucus; the blindness, or the deafness, or the paralysis were not proof against some sudden shock or mental impression. Most of the cases so carefully described by writers on military medicine are now mere matter of history, and are hardly likely to occur again. And the reasons for this are twofold. First; the inducement for deception is practically gone. In former days, when the soldier's pay was small and his hygienic condition bad, discharge from the service as an invalid was eagerly prized as a means of escaping irksome duty, but things have greatly changed for the better of late years. Not only is the emolument and the comfort of our army vastly increased, but short service and the Reserve enables men to retire early into civil life, whilst the abolition of bounty has removed the principal pecuniary inducement for frequent desertion and re-enlistment. It is now found much easier for a man simply to desert than to go through any elaborate process for the personification of disease. Again, the savage process of forcible impressment for naval service was naturally productive of many attempts to escape from the hard work and ferocious discipline of our men of war. Secondly; the process of science and improved means of diagnosis have rendered the task of the impostor difficult, if not

well-nigh hopeless. Feigned blindness can hardly resist the test of the ophthalmoscope; electricity will clear up many apparently anomalous nervous symptoms; the stethoscope and the sphygmograph will tell us the real condition of the heart; and careful observation will detect the rougher attempts to deceive. Again, malingering may often be exposed by examination under chloroform or ether. We are not likely now to be taken in by a piece of liver tied to the breast to simulate cancer, or by an artificial nasal polypus; and although skin-diseases and ulcerations may be made or kept up by local applications, we only require a suspicion to cross our minds to put us on the right track for discovery.

We are not, however, to suppose that all attempts at deception have finally passed away, that feigned diseases are now things of the past. Anyone whose practice lies among prisoners or soldiers or schoolboys will very soon be convinced to the contrary. Experience, however, will soon show him what the schemers are, and enable him to circumvent their endeavours, and the range of symptoms simulated will soon be found to be singularly narrow. Subjective sensations are of course very difficult to detect, and if a headache or pain in the back or leg or arm, be complained of by the sufferer, real or assumed, we may often find it best for our own reputation to give him the benefit of the doubt. A case which happened to the writer whilst medical officer to Rugby School, forcibly illustrates this position. A little boy complained on several successive mornings of most severe pain in the right calf, rendering him almost or quite unable to walk. Inspection could discover nothing wrong, there was no redness nor tenderness and he had no recollection of any injury. Some suspicion of malingering was aroused, but it was thought most prudent to allow him to remain at rest. Four days later a red spot appeared about the middle of the calf, followed by a superficial abscess, which broke in due course, giving exit to half an ordinary sewing needle, which had evidently been working its way gradually upwards among the muscles of the leg. How it obtained admittance could not be ascertained. Whilst proceeding, therefore, with due caution, the practitioner must endeavour to hold the balance between an excess of suspicion and a too credulous attitude, remembering that the good of society and of the public service must be fairly considered, whilst all care must be taken not to confound the innocent with the guilty in dealing with disorders which ingenuity has occasionally been enabled to feign.

ROBERT FAUGHARSON.

FEIGNED INSANITY. See *INSANITY*, Feigned.

FESTER.—A superficial supuration resulting from irritation of the skin, the pus being developed in vesicles of irregular figure and extent. The suppurating inflammation caused by a thorn or splinter of wood forced into the flesh is a common example of a fester.

FEVER (*ferreo*, I am hot).—*SYNON.*: *Pyrexia*; *Fr. Fièvre*, *Ger. Fieber*.

DEFINITION.—One of the most remarkable facts in connection with disease, is the rise of temperature which is attendant upon almost

every disturbance to which the body is subjected. This rise of the temperature of the body, when it attains a certain height, and lasts a certain time, is called Fever, and is accompanied by derangement of function attributable to the febrile condition itself, and in a measure independent of the initial cause.

GENERAL CONSIDERATIONS.—Fever plays so important a part in acute disease generally, is accepted so universally as a mark of the severity of the disease, and so often presents itself as apparently the chief antagonist with which the physician or surgeon has to contend, that the attempt to penetrate the secret of its essential nature has always been a favourite task, and every school in every age has had its theory of the febrile process. It is only, however, within comparatively few years that exact measurement of the body-heat by the clinical thermometer, combined with chemical examination of the various excretions at different temperatures, and aided by the experimental method of investigation, has furnished the data for such a theory. A minute description of fever in the abstract, distinguishing, as would be required, between phenomena proper to fever, and phenomena due to the condition or lesion on which the fever depended, would be lengthy and so crowded with qualifications and exceptions as to be vague and unsatisfactory. The attempt, indeed, would have a more radical defect. Either some variety of fever must be taken as a type to which other forms are referred, which is vicious in principle, or all the phenomena of all febrile conditions must be enumerated and classified, which would confound the accidental with the essential, and would result in a heterogeneous collection of facts without due relation among themselves.

A mere outline therefore will be given of the principal deviations from normal functional action observed in fever, and the space set apart for the subject will be reserved for an exposition of what is known of the nature of the febrile process.

DESCRIPTION.—In every attack of fever there are traceable the three stages of invasion, domination, and decline, with or without an antecedent period of incubation. They may all be run through in the course of a few hours as in a paroxysm of ague, or they may extend over weeks.

The period of invasion is characterised by a rising internal temperature while the surface may remain cold and pale, the patient feeling chilly and suffering from rigors or shivering; the pulse is frequent, but generally small and long, from contraction of the arteries. During the dominance of fever the temperature remains high, the skin is hot, and the shiverings are replaced by a subjective sense of heat, the pulse is now full and bounding from relaxation of the arterial wall. The decline is indicated by a falling temperature, a softer and less frequent pulse, and by a return towards normal conditions generally, it may be initiated or accompanied by a critical sweat or other evacuation. Death may take place at any period of the disease.

Taking the temperature as the index of the duration and character of each stage, we may find it in the first stage rising abruptly or

gradually, continuously or with remissions. If the invasion extends over several days as in enteric fever, nocturnal exacerbations and morning remissions are, as a rule, observed. A rapid rise of temperature is usually continuous, or nearly so. When the opportunity occurs of making the observation, as in intermittent or relapsing fever, or when fever is experimentally induced in animals, or in man by surgical operation or accidental septic inoculation, the increased heat is found to be the initial phenomenon, preceding the rigors and all other symptoms.

The end of the period of invasion, and the setting in of the stage of dominance, is more distinctly marked by the change in the character of the pulse, and by the determination of blood to the surface, together with the substitution of the subjective sensation of heat for that of cold, than by the thermometer.

During the dominant stage the temperature remains at, or oscillates about, a given point, and the fever is considered to be moderate if the morning temperature is 102° or under, and the evening not above 103° ; to be high when it ranges between 103° in the morning and 104° in the evening, and to be severe when these limits are exceeded; while, with rare exceptions, a temperature of 106° indicates great danger. As the stage advances, the heat may gradually rise or fall, the oscillations being slight or considerable, and at times irregular and extreme. Except when the fever is due to local inflammation, or to continual entry into the blood of morbid particles or fluids, the duration of the dominance is usually in proportion to the time occupied by the invasion.

The decline again is generally abrupt, and has the character of a *crisis* when the invasion has been rapid, and is protracted when it has been gradual.

A fatal termination may be ushered in by hyperpyrexia, more commonly the temperature falls below the normal point and there is collapse.

The pulse is always increased in frequency by fever, but while during the height of the disease there is usually some relation between the body-heat and the pulse rate, the pulse is often extremely frequent before the temperature has reached its height during the invasion, and it does not in all cases fall with it *pari passu* in the decline. The different stages are marked rather by differences in the character of the pulse than in its rapidity; during the period of invasion the arteries are more or less in spasm, and the pulse is small and long; during the dominance, with certain exceptions, the arterial walls relax, the vessels are large, and the pulse full and bounding; as the fever declines the arteries are still further relaxed, but the action of the heart is less powerful, so that the pulse becomes softer.

Respiration is frequent, following as a rule the pulse; the amount of carbonic acid expired is greatly increased.

The tongue is generally more or less furred, its appearance varying with the degree and kind of fever and with its cause. It becomes brown and dry, or unnaturally red in protracted and adynamic fever, when the teeth and lips may also be coated with sordes. These are always

always thirst and loss of appetite. The bowels are usually confined.

The secretions are all more or less modified. The perspiration may be greatly increased as in acute rheumatism, or apparently checked, causing the skin to be dry and burning. The amount of urine will vary to a certain extent inversely with the amount of perspiration; but the tendency is to increase, and the solid organic matters—urea and other nitrogenised substances—are always considerably augmented in quantity. The chloride of sodium, on the contrary, is diminished.

The characteristic nervous phenomena of the stage of invasion are rigors, which may be slight, and represented only by shivering or chilly sensations, or, on the other hand, may be intensified to convulsion. Severe headache is more common at this period than in the later stage, and there is usually considerable depression. When the fever has reached its height the rigors will have ceased, and there may be little or much delirium according to the severity of the attack, or the idiosyncrasy of the patient, or, again, according to the kind of disease giving rise to the fever.

PATHOLOGY.—The description of the febrile state has been cut short in order to leave place for a discussion of the nature and cause of the febrile process.

This will be facilitated by a brief reference to the production and regulation of the heat of the body in health, and would be comparatively easy had physiologists arrived at a complete and satisfactory solution of this problem. In the normal state the main source of animal heat is blood- and tissue-combustion. Another very slight and unimportant cause will be obstructed motion of the blood in the capillaries of direct conversion of nerve-force into heat we know nothing definite. The interesting and difficult part of the question is that which relates to the regulation of the temperature. It has been found that the changes which evolve heat are most active in muscle, in the nervous structures, and in the abdominal viscera, while in the lungs, any combustion which may take place is not more than will counteract the loss of heat by evaporation and by the expired air. The skin, on the other hand, is the great cooling agent; there is little combustion of its structures and it is continually losing heat by conduction when the surrounding temperature is low, but still more abundantly by evaporation under all conditions of external temperature. Heat is thus abstracted from the blood circulating in, and immediately beneath, the skin. At first sight then it would seem that the mechanism by which the temperature was regulated was extremely simple, and that it was to be found in the vaso-motor system of nerves. There being an internal heat-producing mass of tissue, and an external refrigerating surface, to raise the temperature, the arterioles of the skin are contracted, shutting off the blood, while those of the deeper structures are relaxed, allowing it to reach them in greater abundance; in this way a double influence is exerted, less heat is lost by the skin, and more is produced in the muscles and other internal parts. Conversely, the temperature would be lowered by flushing the skin with blood- which

would thus be exposed to cooling influences— and diverting it from the heat-forming, deep-seated structures. This explanation, however, is inadequate; it is true that the distribution of the blood, superficially or deeply, by means of the vaso-motor nervous system, contrivances largely to the regulation of the temperature, but heat-production in muscle or gland is not directly proportionate, simply to the amount of blood circulating through it, tissue-combustion, and consequent evolution of heat, are excited or repressed by cerebro-spinal nerves not governing the arteries. The nervous system thus intervenes directly in heat-production as well as indirectly through its influence on the circulation, and it has been shown that the stimulus to tissue-change and heat-production is a reflex from peripheral impressions. This is not the place to discuss the question whether there are special thermal nerves and centres, but it may be said that this has not been proved.

Taking the increased heat as the characteristic of fever, the first question which arises is whether this is due to increased production of heat, or to diminished loss. While the diminished circulation in the skin in the early stage, will obviously tend to retain heat within the body, there is now no room for doubt that there is increased heat-production, the temperature rises in spite of profuse perspiration, when of course heat is very rapidly lost, as in acute rheumatism, or when perspiration has been induced by jalap and before a paroxysm of ague (Ringer), and it has been shown by direct experiment that in fever a man raises the temperature of a given quantity of water in which he is immersed more quickly, and to a higher point, than in health (Liebnermeister). It is unnecessary to give other proofs or further refutation of the hypotheses which explain the heat of fever solely by diminished escape of heat from the body.

It may further be taken as certain that the immediate cause of the increased generation of heat is increased blood- and tissue-oxidation. This is shown by the increased products of combustion given off in the different excretions. The febrile elevation of temperature is attended at once by increase in the amount of carbonic acid expired. This is more marked during the rise than when the heat has attained its maximum, because the increasing temperature expels the gases of the blood, and the greater rapidity of the circulation sends the blood more freely and quickly through the lungs, and exposes it more to the air. At first there will thus be eliminated not only the carbonic acid formed under the influence of the febrile process, but that which was held in solution by the cooler blood, and is driven off as its temperature rises; when the expulsion of dissolved carbonic acid is completed, the amount excreted will be diminished by so much, but it still remains larger than at the normal temperature.

A similar indication of increased tissue-combustion is furnished by the urine. The amount of urea is usually absolutely increased, notwithstanding a diminished consumption of nitrogenised food; or if the urea itself is not excreted in larger quantity, there is more nitrogenised

waste in other forms. The total of nitrogenised matter contained in the urine is always augmented by fever.

The real difficulty of the problem arises when we inquire what is the cause of the increased tissue-combustion. It has been already stated that the distribution of the blood to the deep structures and organs and to the skin respectively is not a sufficient explanation of the physiological balance of heat, but it might be supposed that the greater rapidity of the circulation in fever renewing the supply of oxygenated blood within the structures more frequently and more freely, would account for the greater oxidation. The rise of temperature, however, is not in proportion to the flow of blood through the vessels, and hyperpyrexia is often coincident with a failing circulation, the heat, indeed, apparently in some cases actually increasing after death.

One step towards the solution which may be considered certain is that the nervous system is concerned in the maintenance of the heat of fever. Each disease has its own characteristic range and variations of temperature, and this fact alone, that febrile heat is not vague and irregular, but that there is the substitution of a morbid for a normal balance, is evidence of nervous control. Numerous observed facts and experiments point to the same conclusion. We need only mention the hyperpyrexia often resulting from injuries to the brain, and following section of the cord in the cervical region.

Another item of positive knowledge obtained by experiment is that pyrexia may be excited by the introduction into the blood of septic or other matters, which, it is important to note, need not be particulate, but may be diffusible fluid. The increased heat may therefore be independent of capillary embolisms and of bacteroid or other organisms.

Now in disease or after injuries we have almost always both causes in possible operation—an impression on the nervous system, and the entry of altered organic matters into the blood. In endeavouring to assign prominence to one or other, we have, on the one hand, such facts as the hyperpyrexia of cerebral lesions, which cannot be due to blood-contamination, and, on the other, the teachings of antiseptic surgery, which demonstrate that absorption of putrescent discharges is the great cause of surgical fever. It still remains to be determined whether the presence in the blood of foreign matters gives rise directly to increased activity of oxidation, or whether the poison, as we may call it, produces this result through its action on the nervous system, either by affecting the nerve-centres themselves, or by producing irritation in the capillaries, which is carried to the nerve-centres, and reflected along efferent nerves. In the present state of our knowledge this question cannot be definitely settled.

If a theory of the febrile process is to be formed it must be based upon a theory of the relation between the nervous system and the processes of nutrition and oxidation, and especially the latter. Numerous facts of disease and of experiment point to the conclusion that the circulation of duly oxygenated blood through the

tissues at the usual rate would, without some check to oxidation, result in more rapid tissue-change and the production of a higher temperature than the established norm. The restraining power is supplied by the nervous system, the loss of this influence being illustrated in hyperpyrexia. The mode in which the nervous system acts may be represented as being through the tension maintained in the nerve-centres. All nervous actions have the character of phenomena of tension, and the tension generated in the cells is sustained in the nerve-fibres to their peripheral terminations, where they are merged in the structures, and so blended with them that all nutritive and oxidative changes are common to the nerve-endings and the tissues in which they end. If we suppose that the nerve-tension can modify chemical action, as can electrical tension or thermal conditions, and that, *vice versa*, the nutritive and oxidation changes in the tissues can influence the tension of the nervous structures, we can represent to ourselves the interaction between the nervous system and the blood and tissues in the febrile process. When from disease or injury of the great nerve-centres their power of maintaining tension is abolished, and their influence destroyed, the affinities of the blood and tissues have unrestricted play, and the result is hyperoxidation and pyrexia. When, on the other hand, septic matters or other substances are introduced into the blood, acting as ferments or in some other way, they increase oxidation, and directly raise the temperature, overpowering the restraining influence of the nerves until this is reinforced, which may possibly occur through increased evolution of energy, resulting from the increased activity of metamorphosis. We cannot, however, here develop or fully elaborate this hypothesis.

TREATMENT.—The treatment of fever is of course primarily directed to the removal of the cause on which it depends, but together with the measures adapted to this end are usually employed means for the moderation of the febrile process as such, and these may at times take the first place. We can do little more than mention the more important of them, taking first what may be called the general methods, and promising that rest in bed, simple food, &c. are taken as understood. Venesection is now scarcely ever practised as a means of combating fever. Purgatives are often useful as are also diaphoretic and diuretic salines, with abundance of water to drink, either alone or in the form of some agreeable tonic. Freer action of the secretions, which is the object of these remedies, is of service in removing the increased products of oxidation, the water taken co-operating by acting as a solvent and vehicle, and it is possible that medicines which promote this activity may directly bring down the temperature. When, for example, perspiration has been induced, a coincident fall of temperature may be due more to some change antecedent to the perspiration than to the loss of heat by transpiration and evaporation.

Of special measures for the reduction of febrile heat when this is becoming dangerous, either from its intensity or duration, the first to be mentioned is the cool or cold bath. This should be resorted to in all cases of hyperpyrexia, from

whatever cause; its efficacy, first established in the high temperature of acute rheumatism and enteric fever, has been proved also in cases of septic hyperpyrexia after ovariotomy, and even in injuries to the brain. Here the water may be positively cold. When the bath is employed to control temperature, not dangerous from its height, but from its duration, as in enteric fever, it need not be lower than 70° or 65° Fahr. An ice-cap devised by Mr. Knowley Thornton, for applying cold of 32° to the entire head, has been found useful in hyperpyrexia following ovariotomy.

Many alkaloids have the property of reducing febrile temperature when taken in large doses. The most powerful, and the one most generally employed to combat fever, is quinine. When given for this purpose, it is administered in doses of from ten to twenty or even thirty grains once in twenty-four or forty-eight hours, or three to six grains of the neutral sulphate may be injected under the skin. Salicylic acid has a remarkable influence on the temperature in acute rheumatism, and some effect, though far less marked, in fever from other causes. It may be added that when pericarditis has come on in rheumatic fever, this drug usually altogether fails to influence the temperature. The only other drug which need be specially mentioned is aconite, the mode of action of which is totally different from that of quinine, and of which it may almost be said that it antagonises the fever process rather than reduces temperature, its most marked influence being on the force of the heart and the contraction of the arteries. The opportunity for the manifestation of its powers occurs in the early stage of catarrhal fever, the result of chill. Given in frequent small doses (a drop or two of the tincture every five minutes till twenty minims or half a drachm has been taken) when the temperature is rising, the pulse frequent and hard, with headache and burning skin, the effects are often striking. When a local inflammation is established, it is no longer of much use, and when the fever is protracted, as in enteric fever, or when there is pneumonia, it may be dangerous, from its depressing influence on the heart. W. H. BROADBENT.

FIBRILLATION, Muscular.—A localised quivering or flickering of muscular fibres. See *MOTION, Disorders of*.

FIBRINOUS CLOT. See *CLOT*.

FIBRINOUS CONCRETION. See *CONCRETION*.

FIBROID DEGENERATION.—A morbid change which consists in the substitution of a tissue somewhat resembling fibrous tissue for other structural elements; some pathologists consider this change to be of the nature of a degeneration. See *DEGENERATION*, and *CANCER*.

FIBROID PHTHISIS.—A name given to certain cases of phthisis in which a considerable development of fibroid tissue is found to occur in the lungs. See *PHTHISIS*.

FIBROMA.—A form of tumour composed of fibrous tissue. See *TUMOUR*.

FILARIA SANGUINIS-HOMINIS.

FIBRO-PLASTIC GROWTH.—A form of new growth, composed of fibro-plastic elements. See *TUMOUR*.

FIGUS UNGUIUM (*Scirp.* a fig; *unguis*, a nail).—A disease of the posterior wall of the nail. See *NAILS, Diseases of*.

FILARIA SANGUINIS-HOMINIS.—In the article *CHYLURIA* a full account is given of the embryo-*Filaria sanguinis-hominis*, the hæmatozoön which is ordinarily found associated with this disease. Since that article was written, the writer has succeeded in obtaining what is beyond question the mature form of the helminth. On the 7th August, 1877, two living specimens were found—a male and a female—in the person of a young Bengalee, affected with well-marked nævoid elephantiasis of the scrotum, associated with the presence of embryo-filarie in the blood.¹ The diseased tissues were removed by the late Dr. Edward Gayer, of Calcutta, to whose kindness the writer is indebted for the opportunity of examining them. Unfortunately the specimens were much injured by the needles used to tease the clot in which they were found; the terminal ends of the male could not be found, nor the caudal end of the female, although the fragments of both specimens manifested active movements. They were attenuated, fine, thread-like worms, of a white colour; the cuticle was smooth and devoid of transverse markings.

The fragment of the male specimen measured half an inch in length, and $\frac{1}{16}$ transversely; it was thinner than the female, but of firmer texture, and manifested

FIG 18. Anterior end of *Filaria sanguinis-hominis*.—Mature form $\times 100$ diameters.

FIG 19. A portion of the mature *Filaria sanguinis-hominis*, showing intestine tubules filled with ova in various stages of development, also the intestinal tube. $\times 100$ diameters.

greater tendency to coil. The intestinal canal measured $\frac{1}{16}$ " [0.39 mm.] across, and the spermatheca $\frac{1}{16}$ " [0.16 mm.].

The length of the portion of the female worm

¹ For further details, see *Indian Medical Gazette* Bhop. 1, 1877; *The Lancet*, Sept. 29, 1877, and *Generalist für die medicinische Wissenschaften*, No. 43, 1877.

which had been secured was $1\frac{1}{2}$ ", and its greatest width about $\frac{1}{16}$ ". It was packed with ova and embryos in various stages of development; the latter, especially those which were mature, manifested active movements. The head is slightly club-shaped; the mouth does not manifest any very distinctly marked labial sub-divisions, nor are there any chitinous processes evident either before or after death.

The following measurements may prove useful to future observers:—

	of an in.	mm.
Oral aperture to end of oesophagus	$\frac{5}{16}$ or	'45
Diameter of oral aperture	$\frac{1}{16}$	" '008
Width of extreme end (anterior)	$\frac{1}{8}$	" '047
Ditto anterior end at 'neck'	$\frac{5}{16}$	" '045
Ditto opposite junction of intestine with oesophagus	$\frac{3}{16}$	" '112
Ditto about $\frac{1}{4}$ inch from anterior end	$\frac{1}{4}$	" '162
Width where packed with ova and embryos	$\frac{1}{16}$	" '25
Width of uterine tube filled with ova	$\frac{5}{16}$	" '112
Ditto alimentary tube	$\frac{5}{16}$	" '037

The ova do not possess any distinctly marked 'shell'; from the smallest to the largest nothing but a delicate pellicle can be distinguished as enveloping the embryo in all its stages. The average of six measurements of the least advanced kinds of ova, that is, those in which the outline of the embryo was not distinctly evident, was $1\frac{1}{16}$ " [$\cdot 018$ mm.] by $\frac{1}{16}$ " [$\cdot 012$ mm.], whilst the

FIG. 20. Ova and embryos of *Filaria sanguinis-hominis* x 300 diameters.

average measurements of three ova in which the embryos were visible were $\frac{1}{16}$ " [$\cdot 017$ mm.] by $\frac{1}{16}$ " [$\cdot 013$ mm.]. When the latter, after having arrived at this stage of development, are examined during life, it is in many instances difficult to state whether they are to be considered as freed embryos or not, as the 'shell' has become so attenuated and translucent as only with difficulty to be distinguished. It is possible that when the embryo acquires worm-like proportions the envelope is not lost in this species so long as it continues in the blood.

With regard to the relation of the mature *Filaria sanguinis-hominis* to pathological phenomena nothing very decisive can be said, but when it is considered that the blood of some animals is found occasionally to harbour minute, active organisms, in great numbers sometimes, without appreciable injury, it seems not improbable that the parental forms of nematoid hematodes, rather than the embryos, may be the more hurt-

ful to the animal economy. The lesions induced by the growth of the *Filaria sanguinolenta* in the arterial walls of dogs, to which the writer has elsewhere drawn attention, appears to lend support to such a view.

In 1877, Dr. Cobbold announced that Dr. Bancroft, of Brisbane, had discovered specimens of what were believed to be mature forms of the *Filaria*. A dead specimen was found in a lymphatic abscess of the arm, and on a second occasion four living specimens were obtained from a hydrocele of the spermatic cord. They were of the thickness of a hair and from 3 to 4 inches in length. A minute description of them by Dr. Cobbold appeared in the *Lancet* of the 6th October, 1877. The persons from whom the specimens were obtained had not suffered from either chyluria or nevus elephantiasis, nor were they known to harbour embryo nematodes in their blood.

TIMOTHY RICHARDS LEWIS.

FILARIÆ (*filaria*, a thread).—A genus of nematoid worms, not very clearly defined, but which contain a variety of thread-like parasites whose body is of uniform thickness throughout, and at least fifty times longer than it is broad. Under this head are often included several human parasites such as the *Dracunculus*, or Guinea-worm (*Filaria medusarum*), and the lung strongyle (*F. bronchialis*), in addition to a variety of larval or sexually immature nematodes, whose generic relations are only very imperfectly understood. In the latter category may be placed Bristow and Ranney's entozoon (*F. trachealis*); Von Nordmann's eye-worm (*F. oculi-humani* or *F. lentis*), the *lar*, infesting the eyes of the Angola Coast and Gaboon negroes (*F. lat*), and lastly, the nematoid hematode (*F. sanguinis-hominis*) recently described by Lewis in his illustrated memoir. It may be doubted if any of the above-mentioned parasites ought to be included in the genus *Filaria*, as understood by modern helminthologists, but, practically, it is still found convenient thus to speak of them. The *Dracunculus* will be found described under GUINEA WORM, whilst the microscopic nematoid infesting the blood will be found noticed under the articles HEMATODIA, CHYLURIA, and FILARIA SANGUINIS-HOMINIS. T. S. CONNELL.

FISH-SKIN DISEASE.—A synonym for ichthyosis. See ICHTHYOSIS.

FISSURE (*fudo* I cleave).—A narrow and superficial crack or solution of continuity, observed on the skin and mucous membranes, and especially near the line of junction of these structures, as on the lips and anus. See ANUS, DISEASES OF, and CHAPS.

FISTULA (*fu'tula*, a pipe).—A narrow track or canal leading from a free surface, and extending more or less deeply to some seat of local irritation, or it may be constituting an abnormal com-

¹ The researches of Dr. Manson, of Amoy, confirmed by Dr. Lewis, show that embryo *Filaria* in the blood are killed by the mosquito, or other intermediary host; undergo developmental changes; and are discharged into water with the larva of the insect. Infection probably occurs through this medium. Dr. Manson has recently stated (*Medical Times*, June 1881) that the habitat of the parent *Filaria* is in the lymphatic trunks.—Ed.

communication between two or more cavities, as in the case of vesico-vaginal or recto-vaginal fistula. See ANOMALY.

FISTULA IN ANO See RECTUM, Diseases of.

FIT.—A popular synonym for a sudden seizure characterized by loss or disturbance of consciousness from any cause, with or without convulsions. (See CONVULSIONS, EPILEPSY, Hysteria, and SYNCOPE.) The term is also applied to a sudden or acute seizure of certain diseases, such as gout, asthma, and ague.

FLATULENCE (*flatus*, a puff of wind). **SYN.**: *Fr. Flatulence*, *Ger. Flatulenz*.

DEFINITION.—The undue generation of gases in the stomach and intestines.

ÆTIOLOGY.—The principal cause of flatulence is fermentation or decomposition of the contents of the stomach and bowels—a condition usually induced by embarrassment of function. Hence it is a common symptom in dyspepsia—especially the atonic forms as met with in the debilitated and the aged—constipation, gastritis, enteritis, hepatic disorders, intestinal obstruction, &c. When flatus is generated too rapidly to be accounted for by fermentation, as in hysteria, hypochondriasis, and other forms of nervous delirium, it has been ascribed, but incorrectly, to secretion of gases from the mucous membrane.

SYMPTOMS.—The clinical phenomena vary as flatus is retained or discharged, and with the seat of its formation, which is chiefly in the stomach or intestines. In the former the concomitant symptoms are those of dyspepsia, and in the latter there is usually constipation. As a rule, however, flatulence pervades at the same time more or less all the hollow viscera, and indicates torpor of the digestive organs. It is apt to lead to these further evils:—(a) *Pain* from distension or from irregular and forcible contractions of the walls—hence gastralgia and colic are apt to arise, (b) *arrest of the normal movements* of the stomach and intestines, and consequent accumulation within them of fermentable matters, with further generation of gases, leading to paralytic distension, hence dilatation of the stomach and colon, tympanites or meteorism, and aggravation of pre-existing dyspepsia or constipation nervosa; and (c) *pressure on adjacent organs*, e.g. on the heart and lungs, inducing palpitation and irregular action of the heart, precordial anxiety, faintness, vertigo, dyspnoea or even asphyxia.

In tympanites there is a rapid generation of flatus, which overpowers the contractility of the hollow viscera, and the abdomen is round, tense and tympanitic. When this condition is accompanied by fever and diarrhoea typhoid fever should be suspected; but if fever be absent while there is bilious or serous vomiting, probably intentional obstruction exists—intussusception, internal strangulation, &c.

TREATMENT.—(a) *Increased flatus should be dissipated* by friction of the abdomen with stimulating liniments, and gentle kneading of the most distended parts; large draughts of hot water; spirit and hot water, ammoniac ether, or spirit of chloroform; aromatic stimulants—ginger, cloves, mint, cake, cognac, camphor, aniseed, &c.

When flatulence is chiefly intestinal, enemata containing laudanum with aniseed, turpentine, or rue; and pilula aniseedae compo with extractum nucis vomice, and an aperient are the most useful measures.

(b) *The generation of flatus should be arrested.* Fermentation may be checked by sulphate of sulpho-carbide or soda, sulphurous acid, carbonic acid, creosote or charcoal—from the poplar or vegetable ivory—immediately after food, and by correcting and toning the digestive organs. Food likely to ferment or lodge, such as starch, sugar, fruits or vegetables, and warm liquids—especially tea and soups—should be avoided, the meals should be well masticated and solid food should be taken sparingly at the close of an hour after. In some cases, however, flatulence is connected with an insufficient supply of fluids and can only be met by increasing it. Alkalies—carbonate of magnesium, soda, or lime—and bitters, especially stylicum, are often useful in the flatulence of hysteria, hypochondriasis, the very nervous and the aged (Froussard, Niemeyer), but perhaps the best results follow alkalies with nucis vomice and bismuth an hour before, and hydrochloric acid alone or with Liebreich's Pepsin Essen or other reliable preparation of pepsin after food. It is also essential to see that the action of the liver is healthy. GEORGE OLIVER.

FLEXION (*flecto*, I bend)—A bending. This term is applied either to the act of bending or in some methods of treatment, for example the cure of an urism or the reduction of dislocations, or to the condition in which parts are bent, as the result of disease or of disorder, as when the limbs or certain internal organs are bent upon themselves. See WOUND, Diseases of.

FLOODING—A popular term for excessive discharge of blood from the womb. See MENSTRUATION, Disorders of, and PURGANTS, Disorders of.

FLUCTUATION (*fluctus*, a wave)—A physical sign consisting in a wave-like or undulating sensation. It is elicited by a peculiar mode of palpation with the one hand while percussion is made with the fingers of the other; and is due to the presence of a fluid in a natural cavity such as the peritoneum, or in an abnormal closed space such as a cyst (see PHYSICAL EXAMINATION). The term fluctuation is used by the surgeon in a sense which differs in signification, being applied to the sensation of the presence of a fluid which may be felt when alternate pressure with the fingers is made, as over the seat of an abscess. See ABSCESS.

FLUKE—In its original signification this term means anything flat, but, in connection with internal parasites, it refers generally to the common liver-fluke and its allies which happen to be more or less flat or leaf-shaped. The liver-fluke belongs to the genus *Fasciola*, though more commonly spoken of as a *Distoma*. Some of the flukes of man, as well as of animals, have a rounded form quite unlike that shown by the ordinary liver-fluke. With one or two notable exceptions, the flukes are destitute of clinical importance. Under this head must

also be mentioned a remarkable snake recently discovered by Dr. Lewis in India, and called by him *Amphistoma hominis*. As there is ground for believing that several allied species (*A. flavescens*, *A. Collesii*, &c.) prove injurious to elephants and horses it is possible that the human amphistome may be productive of severe intestinal mischief. See DISTOMA, and BILHARZIA.

T. S. CORBOLD.

● **FLUXOR PLUX** { (Latin).—A flow or excessive discharge from a mucous surface through any of the natural passages of serum, blood, mucus, pus, or the various secretions. As illustrations of fluxes may be mentioned salivation, bronchorrhoea, bilious flux, diarrhoea, dysentery or bloody flux, cholera, and leucorrhoea or white flux (*Flux albus*).

FŒTUS, Diseases of the.—Two classes of abnormal conditions are seen in the fœtus, namely,—those which depend upon some interference with the process of development, such as malformations, monstrosities, &c. and those which are the result of disease. This article treats of the latter only.

1. *Amputation*.—Amputation, partial or complete, of fetal limbs, may take place from constriction of the limb by a band of the amnion. An attempt at reproduction of the lost limb is sometimes seen, in the shape of rudimentary fingers and toes, projecting from the stump. That such a stump is the result of amputation is proved by the fact, that the part cut off has been found in utero.

2. *Spontaneous fractures and dislocations*.—Fractures and dislocations occur in utero, the latter being the more rare. They are due to some condition of the bones and ligaments respectively, leading to mechanical fragility of those structures, for they are always multiple and are not accompanied with bruising of the adjacent soft parts.

3. *Tumours*.—New growths are met with in the fœtus—cysts of various kinds, fibromas, lipomas, &c. That most peculiar to the fœtus is a tumour situated over the coccyx, which may be as large as a fetal head. Such tumours are spherical or ovoid in shape, elastic in consistence and present rounded inequalities on the surface. On section they are found to consist of strong fibrous trabeculae, in the meshes of which are numerous small cysts lined with epithelium. It is thought by many that they originate in Luschka's gland. Another special kind of tumour is that known as a *fœtal inclusion*—a swelling usually on the lower part of the trunk, and containing some part of another fœtus, more or less imperfectly developed.

4. *Inflammation of serous membranes*.—This form of disease may occur in the fœtus such as pleurisy and peritonitis. The morbid anatomy of these changes does not differ from that in the adult. Peritonitis is often found associated with syphilis, and it appears to be almost always fatal to the fœtus.

5. *Visceral Inflammation*.—Inflammation of the lungs has been met with, in the form of grey or white lobular hepatization. It is most frequent in syphilis. Enteritis has also been described.

Various malformations of the heart which are met with can be explained by supposing the occurrence of endocarditis during fetal life; but there is no proof that the fœtus is subject to rheumatism. Virchow describes encysted aneurysms.

6. *Specific Fevers*.—The morbid changes of *catarrh fevers* have been found in the fœtus. In pregnant women suffering from *intermittent fever*, paroxysms of convulsive movements of the child have been felt to occur as regularly as the attacks of ague in the mother, and the child when born has been found to have a large spleen. Children have also been born with skin-eruptions thought to resemble those of *measles*, *scarlatina*, and *smallpox*. The facts as to the last-named disease are the most numerous and probable. The eruption of variola in the fœtus differs somewhat from that seen after birth, because, the skin of the fœtus being bathed with fluid, no crusts form, and the pustules run a course like those on mucous membranes.

7. *Diseases of the Skin*.—The fœtus is subject to skin-diseases. Pustules of erythema; patches of erythematous redness; ulceration of the skin, and syphilitic eruptions have been seen. Intra-uterine ichthyosis is met with. Children have been born jaundiced, but only by mothers themselves suffering from that disease. But women with jaundice do not always bear jaundiced children, jaundice is not necessarily fatal to the fœtus.

8. *Syphilis*.—Syphilis leads to various lesions in the fœtus, and while it usually proves fatal, the subjects of it that may survive till birth are feeble and badly nourished. Flat tubercles occur on different parts of the skin, especially round the mucous orifices; and pemphigus, affecting chiefly the palms of the hands and the soles of the feet may be seen. The occurrence of peritonitis has already been mentioned. Yellow mottled nodules, of varying size and number, may be found in the liver, as well as similar nodules in the lungs. A peculiar change has been described in the thymus gland, in which this structure externally appears healthy, but when cut into and compressed exudes a whitish puriform fluid. Other changes have been recorded, affecting the spleen, pancreas, and suprarenal capsules but they are not distinctive. Changes in the bones have also been described, consisting of an osteochondritis, affecting the ends of the long bones, most frequently the lower end of the femur.

9. *Rickets*.—Rickets is met with in utero. The changes it produces are like those seen after birth. It is thought to be one of the causes of spontaneous fractures.

10. *Tuberculosis*.—Tuberculosis sometimes commences in the fœtus, tubercles having been found in the mesentery and in the lungs.

11. *Dropsy*.—Dropsy is met with in the fœtus, sometimes of the serous cavities, of which hydrocephalus is the most common. It is often associated with rickets. Next in frequency comes ascites, and lastly hydrothorax, which is very rare. These affections may destroy fetal life in utero; but they more often lead to death because they render destructive operations necessary before delivery can be accomplished. General anasarca is also met with, and there is reason to believe that it depends upon disease of

the placenta, impairing the excretory function of that organ. It is always fatal, if not before, within a few hours after birth.

15. *Visceral diseases*.—Hypertrophy of the liver, spleen, or kidneys may occur in the fetus. Cystic disease of the kidney may be met with, the organ being converted into a mass of cysts containing no trace of secreting structure. Both kidneys are usually affected, and the disease is generally associated with some malformation elsewhere. Hydronephrosis, single or double, along with dilatation of the ureter, or ureters and bladder, has been seen, dependent upon impermeability of some part of the urinary passages. Any of these visceral diseases may form a tumour so large as to impede delivery. None of them can be diagnosed before birth. Concretions of uric acid and urates are not uncommon.

The Causes of Death of the Fetus.—The various causes of death of the fetus *in utero* may now be briefly considered. The first of these is *injury*, as when the mother receives a blow upon the abdomen or has a fall. Such occurrences rarely directly injure the fetus, although this has been known to happen. When they prove fatal to the fetus, they do so by leading to hemorrhage into, or separation of a portion of placenta, and consequent disturbance of the fetal circulation. *Poisons* in the mother's blood, such as lead, urea, or carbonic acid (as in the case of heart-disease with cyanosis), may lead to death of the fetus. *Syphilis* has already been referred to. Epileptiform convulsions may destroy fetal life, either by asphyxia, or by leading to hemorrhage into the placenta. Extreme *anæmia* and the *cancerous cachexia*, are among the causes of fetal death. Any kind of disease attended with *pyrexia* will also destroy fetal life if the temperature rise high enough. A temperature exceeding 105° Fahr. appears to be invariably fatal to the fetus. Certain diseases of its appendages may lead to death of the fetus, such as fatty degeneration, or œdema of the placenta, obliteration of the umbilical vessels, or interruption of the circulation in the cord by knots in it, or pressure upon it. It is believed that there are some diseases of the mother's uterus which lead to death of the fetus, but what they are is not known. It is said that some women acquire a habit of having dead children. This means that there are cases in which an apparently healthy woman will repeatedly have dead children, the cause of whose death a skilled observer cannot find out. In other words, there are causes of fetal death as yet unknown.

The Consequences of Death of the Fetus. A dead fetus while retained *in utero*, and thus protected from the air, does not putrefy, but undergoes a process of maceration. The whole body becomes soft and flaccid, its tissues being infiltrated with fluid, but it has no putrid odour. The skin presents bullæ filled with reddish serum, and the epidermis is readily detached with slight friction. The surface is of a cyanotic colour, which after exposure to the air becomes of a more or less bright red; it is not greenish, as is seen in putrefaction. The cellular tissue is infiltrated with bloody serum. The viscera have lost their distinctive tints, and become of a reddish-brown colour. The cranial bones are

abnormally mobile, overlapping one another to a greater extent than normal, and the pericranium may be stripped off them. These appearances are much the same, whatever be the cause of death, but they vary in degree according to the length of time which has elapsed since death.

Besides the diseases of the fetus described above there are others which are not fatal, and the chief interest of which lies in their course and treatment after birth. These are discussed in other articles, and for that reason are not mentioned here.

G. E. HERMAN.

FOLIE CIRCULAIRE (French).—This term is applied by the French psychological physicians to a variety of insanity characterized by alternations of excitement and depression. The patient passes through an attack of mania or perhaps an ordinary character but when he appears to have recovered he sinks into melancholia, and thence emerges again to become maniacal and excited. The duration of each stage may vary from weeks to months, sometimes one state will follow the other immediately, in other cases a period of convalescence will intervene, during which the patient appears well, and can hardly be considered insane. Yet the prognosis is extremely unfavourable in all such cases, and it is of great importance in estimating the extent of recovery of a patient that it should be clearly ascertained that the attack is not one of a series following one another in the manner mentioned. G. F. BLANDFORD.

FOLLICLES, Diseases of (folliculus, dim of follic, a bag).—The name 'follicle' has been applied to a great variety of different structures which have in common the shape of a bag or sac, whether circular or elongated in outline, for example—the Graafian follicles, the lymphatic (Peyrian) follicles of the intestine, and the follicles of the mucous membrane of the stomach, intestine, and uterus. The name has been further extended to include glands somewhat more complex in structure, such as the sudoriferous glands or sweat-follicles, the sebaceous follicles, and the tonsils, as well as the saccular depressions in which the hair and the teeth take their origin. The name *Synovial Follicles* is sometimes given to processes of synovial membrane invaginated in the articulation of a joint.

For an account of the diseases of these various structures, the reader is referred to the several articles under which they are discussed, but so far as the true follicles are concerned, the following may be said to be the principal morbid changes to which they are liable:—Atrophy; Hypertrophy; Obstruction, and Distension; Inflammation, Ulceration; Cystic Disease; New Growths; Tubercle; Acute Specific processes, such as the typhoid, and Parasitic disease.

FOMENTATION (foveo, I keep warm). SYNON.: Fr. *Fomentation*, Ger. *Bilung*.

DEFINITION.—Fomentation is the application to the surface of the body of flannels, cloths, or sponges moistened with hot water, either pure or containing some medicinal substance in solution.

ACTION.—The action of a simple fomentation is the same as that of a poultice. By its warmth and moisture it tends to relax the muscular fibres

of the skin, and often the cuticle, thus relieving tension, and diminishing pain and irritation. In the early stages of inflammation it favours resolution, by maintaining the temperature and promoting active circulation through the area which has suffered from the injurious influence which has started the process. In the later stages it promotes and hastens suppuration, by causing dilatation of the vessels, and hastening exudation and cell-multiplication. A fomentation is superior to a poultice in lightness and cleanliness, but unless care be taken it loses its heat more quickly. This disadvantage may be overcome by covering the fomentation with a thick layer of cotton-wool.

APPLICATION AND USES.—A fomentation is thus applied:—A piece of coarse flannel, or of spongio-piline, sufficiently large to cover the affected part when folded into two layers, is put into a basin and boiling water is poured upon it. It is then lifted from the basin with a pair of tongs or some convenient instrument, and dropped on the wringer. This is a stout piece of towelling with a stick attached to each end. The sticks then being twisted in opposite directions, as much water as possible is squeezed out of the flannel. It is then immediately placed on the affected part, and covered with a large piece of oiled silk or indiarubber sheet extending at least one inch on each side of it. Over this may be placed a thick layer of cotton-wool, and a bandage. If the flannel be not squeezed sufficiently dry it will wet the bed or clothing. If not sufficiently covered with oiled silk and wool it soon becomes cold. Whatever means may be taken to retain the heat of a fomentation, it can be kept above the temperature of the body only for a few minutes. If, therefore, the full effect of fomentation is desired to be obtained, the flannel must be changed every twenty minutes. In many parts a sponge, or a piece of spongio-piline, wrung out of boiling water forms a most convenient form of fomentation. When the fore-arm or hand is affected, a bath of hot water may be substituted for fomentations. The temperature of the water must be maintained by the repeated addition of small quantities of boiling water.

Fomentations are especially useful in all cases of erysipelas and diffuse cellulitis, and in boils. In *peritonitis* they are borne more easily than plasters, on account of their greater lightness. Whenever they can be employed they are superior to poultices on account of their cleanliness. They are not applicable to cases in which there is a discharging wound or abscess, as under such conditions the cloths become foul.

VARIETIES.—If it is desired to add some slight counter-irritation to the warmth and moisture, the fomentation may be sprinkled with turpentine before it is applied. This forms the ordinary *turpentine-stupe*. The sedative action of the fomentation may be increased by sprinkling it with laudanum. The ordinary poppy-fomentation is often used with the same intention. It is thus prepared:—Half a pound of poppy-heads with the seeds taken out is boiled for ten minutes in four pints of water, and the liquid then strained off. The decoction is kept warm over a fire and the flannels dipped in it and applied as before described about every half-hour. The term

'dry fomentation' is sometimes applied to bags of salt, hot bran, or chamomile flowers; or pieces of flannel soaked before a fire and applied hot. These often give relief in cases of intestinal, renal, or biliary colic. **MARCUS BACH.**

FOMITES (*fomes*, fuel).—Substances capable of retaining contagium-particles, and thus of being the means of propagating any infectious disease. The most important fomites are bed-clothes, bedding, woollen garments, carpets, curtains, letters, &c. See **CONTAGION**.

FOOD. See **ALIMENTA**, and **DIET**.

FOOD. **Ætiology of.**—See **DISEASE**, Causes of; and **DIGESTION**, Disorders of.

FORAMEN OVALE, Patency of.—See **HEART**, Malformations of.

FORCIBLE FEEDING.—In the treatment of insanity it not unfrequently happens that we are compelled to administer food by force to patients who, for one reason or another, refuse to take it. The majority of them are melancholic persons who think they ought not to eat, or try to commit suicide by starvation, and many are in a feeble bodily condition when they commence this refusal. Such persons must be fed by force without delay. Strong patients may be allowed a longer time, for many refuse from whim or obstinacy, and hunger will soon overcome their disinclination. Some patients in a state of acute delirium will take no food, they must be fed at once, and it is important that they should be fed without a protracted and exhausting struggle, for they will resist desperately unless completely overmastered. In almost every case feeding should be done early: the sooner it is done, the shorter will be the period during which it will be required. What method is to be adopted? The various plans range from merely feeding with a spoon as one feeds a child to sending food down the œsophagus with a tube passed through the mouth or nose, the patient being restrained in a chair or on a bed by attendants or mechanical restraint. The mode of feeding varies according to the resistance, and no one method is applicable to every case. There is no need to pass an œsophageal tube down the throat of a man whose resistance is passive and easily overcome; on the other hand we occasionally find patients of great muscular strength and unobtainable will, who can hardly be fed with safety in any way except by the stomach-tube. Of these we may speak first. In what position are they to be fed, sitting or lying down? If they are to be held by attendants no doubt the recumbent posture is the one in which the latter can exercise most power. But when a man is so strong that, as we are told, five attendants must hold him, a struggle will not be unattended with danger, for the five are not all acting together, and he gets loose now a leg and now an arm, to the great discomposure of the operator: moreover this struggle repeated three times a day soon renders him a mass of bruises. He should be placed in a strong wooden chair, and by sheets wound round his body, arms, and legs he can be fastened to the chair so completely that he is as incapable of movement as if he were paralyzed.

yet he gets no brains, and the operator acts upon him free from all inconvenience. Some writers advocate feeding by the nose, and prefer this method to passing a tube through the mouth. But if a long tube is used it is apt to get into the larynx, and if the food is pushed into the nose through a funnel or feeder, it is often ejected again. The only advantage of feeding through the nose is that we are not compelled to force open the mouth. This is a work of difficulty if the patient is strong and his teeth perfect, unless we are provided with the screw-key invented for this purpose: with this there is little difficulty, and only banging will injure the teeth or gums. If the patient is properly secured and the head held by an attendant, not between his knees but by his hands. If the œsophageal tube be of good size it cannot enter the larynx. The wooden termination of the tube must be short, so as to allow of its curving. The operator standing in front passes the tube through the hole of the gag, inclining it to the patient's left, so as to avoid the vertebrae. It may be held by the tongue, but at the first inspiration the hold is relaxed, and it glides down the œsophagus. The food may be poured down it by a funnel or pumped down by the pump. The next class of patients, making less resistance, may be fed by Haley's feeder, a glass vessel with a flattened spout which goes over the tongue: the food is emitted, a little at a time, by means of a spring, and finds its way down the gullet. A certain number of patients may be fed by getting a funnel behind the teeth and pouring food into it, and others by holding the mouth open by means of two spoons, and then pouring food in. The objection to the latter method, and to its many modifications, is the time taken up in the operation, whereby great fatigue and exhaustion are produced. G. T. BLANDFORD

FORMICATION (*forma* a nut).—An abnormal subjective sensation referred to the skin, which is described as of a creeping character, and as resembling the crawling of ants upon the surface. See SENSATION, Disorders of.

FOURTH NERVE, Diseases of.—Morbid states of the fourth nerve are shown in spasm or paralysis of the superior oblique muscle which it supplies. Little is known of overaction of this muscle. Clonic spasm in it is seen in rotatory nystagmus. Paralysis is not uncommon. Its usual causes are inflammation of the nerve-sheath from cold; syphilitic affections of the nerve or of its membranes; cerebral tumours &c., pressing on or injuring the nerve at its origin from the valve of Vieussens or in its course around the crus; aneurism, exostoses or growths in the orbit; and degeneration of the nucleus, in common with the nuclei of the other nerves of the ocular muscles.

Symptoms.—Even in complete paralysis of the superior oblique muscle there is little obvious deviation of the affected eye. Movement downwards is, however, defective, and therefore diplopia exists when the eye is moved below a line which runs obliquely downwards from the healthy to the paralysed side, through the point of mid-fixation. Movements which necessitate a downward position of the head are therefore chiefly

interfered with, and it is common for the first discovery of a defect to be that the patient becomes giddy when he goes downstairs, in consequence of seeing two slighter of stairs before him instead of one. The chief visible defect in movement of the affected eye (examined alone) is downwards and inwards because it is when the eyeball is moved in these directions that the superior oblique has most influence on the vertical position of the eyelids. The defect in the rotation of the eyeball is greatest when it is moved downwards and outwards. The diplopia which exists when both eyes look down is homonymous, that is, the image formed by the affected eye is on the same side as that eye. The left eye being higher than the right, its image (the left) appears lower than the right image. The action of the superior oblique being to move the upper end of the vertical axis of the eye inwards, there is in its paralysis an abnormal divergence of the upper ends of the vertical axes, and the double images (being always inverted) will converge, their upper ends being nearer together than the lower. This is due to the obliquity of the false left image, and this obliquity is greatest when the eyeball is moved to the left and downwards, because in this position the rotatory power of the superior oblique is greater, and the obliquity is least in looking inwards and downwards. Thus the convergence of the images is greatest when the difference in height is least, and *vice versa*. When the paralysis of the superior oblique has existed for some time, a secondary contraction of the inferior oblique may cause crossed diplopia in looking upwards.

Treatment.—The treatment of paralysis of the fourth nerve is in the main that of its cause. When due, as it very commonly is, to syphilis, iodide of potassium in full doses, with or without mercury, is necessary. Smaller doses of iodide with quinine or iodide of iron are also useful for rheumatic paralysis. Blisters to the temple in the early stages are useful. A little, but not much, good may be effected by applying the constant current from the eyelid to the forehead (Benedikt), a few cells only being used.

W. R. GOWERS.

FRAGILITAS CRINIIUM (*fragilitas*, brittleness, *crinis*, the hair). See HAIR, Diseases of.

FRAGILITAS OSSIUM.—A diseased condition of the bones in which they are extremely fragile, so that they are liable to fracture from very slight causes. See BONES, Diseases of.

FRAMBOESIA (*framboese*, a strawberry).—SYNON: Yaws, Fr. and Ger *Yau*.

Definition.—Framboesia consists of an eruption of yellowish or reddish-yellow tubercles; which gradually develop into a moist exuding fungus without constitutional symptoms, or with such only as result from ulceration and prolonged discharge, namely, debility and prostration.

ETIOLOGY.—This disease is peculiar to the African race, both in their native country and in the West Indies. Yaws are epidemic; they are also contagious by actual contact, and consequently inoculable. The period of incubation of the poison ranges from three to ten weeks, and, except in rare instances, the disease occurs only once in a lifetime.

SYMPTOMA.—The tubercles begin with little or no hyperæmia, and range in size between that of a pin's head and a prominent mass one or two inches in diameter. Some subside without piercing the cuticle, and disappear without causing disorganisation of the skin. When the cuticle is penetrated, the tubercles assume the appearance of a fungus's mass of spheroidal figure, yellowish or pinkish in colour, and moistened with a dirty-yellow, foetid secretion. At a later period the fungus shrinks in size, and is converted into a yellow and brownish scab, at other times the ulceration extends deeply and widely into the tissues. The subsidence of the eruption is succeeded by pigmented stain, and the healing of the ulcers by a pigmentary cicatrix.

The eruption selects by preference as the seat of its development, the face and neck, the limbs, the feet, and the genital region and is frequently found around the mouth, the apertures of the nostrils, the eyelids and the anus, where it is apt to present a thick fringe of tubercles or a broad prominent band or ridge.

COURSE AND TERMINATIONS.—The ordinary duration of framboesia extends from two to four months, but frequently this period is prolonged to one or several years. When it is irregular in its development the constitution is apt to suffer, ulcers form around the joints, the joints swell, the discharge from the ulcers is excessive, the exhalations of the body are highly offensive, and the patient is crippled for life, or in some instances relieved only by death.

TREATMENT.—The treatment of *sypha*, according to the best authorities, consists in cleanliness, generous diet, the local use of caustic and lotions and diluted nitrate of mercury ointment, and the employment of constitutional remedies, of which the most useful are mercury, with sarsaparilla or a decoction of the woods, iodide of potassium, and tonics. ERASMUS WILSON.

FRANCE, South of.—The eastern part (Mediterranean Coast) is dry and bracing, with a very clear atmosphere. The chief resorts in it are CANNES, MENTON, HYÈRES, and NICE. The western part is moist and mild but variable, the principal places in it being ARCACHON, BIARRITZ and PAU. See CLIMATE, Treatment of Disease by.

FRANZENSBAD, in Austria.—Alkaline sulphated waters. See MINERAL WATERS.

FRECKLES.—**SYNON.**: *Lentiginæ, lentacula*, Fr. *ephelides*; Ger. *Sommerprossen, Sommerfleck-a*.—A freckle is a pigmentary discolouration of the skin, which has received its Latin or technical name from a resemblance in colour, figure, and size to a lentil. It varies in tint from yellow to olive from brown to black, and is met with on the exposed parts of the skin, particularly the face, neck, and hands, and occasionally on the covered parts of the body ('cold freckles'). It is usually found in children and women in whom the skin is sensitive and delicate, and has obtained its German synonymy from its greater frequency in the summer season. See PIGMENTATION, Disorders of. ERASMUS WILSON.

FREMISSEMENT CATAIRE (*fremissement, purring, catarrh*, connected with a cat)

A physical sign felt on applying the hand over the region of the heart or great vessels in certain morbid conditions; and compared to the sensation conveyed to the hand by the purring of a cat. This sign is more commonly known as 'thrill' or 'purring tremor.' See PHYSICAL EXAMINATION.

FREMITUS (*fremitus, a loud noise*).—A group of physical signs, elicited by placing the hand over the respiratory organs, while the patient speaks (*verbal fremitus*), or coughs (*passive fremitus*), or in certain morbid conditions when the patient simply breathes (*rhachitic, and friction-fremitus*). A fremitus may sometimes also be felt over the cardiac region in connection with the movements of the heart, when the surfaces of the pericardium are much roughened. Another form of fremitus is a peculiar sensation called *hydrotic fremitus*, which may be elicited by a special mode of percussion over hydrotic tumours in some cases. See PHYSICAL EXAMINATION.

FRICTION.—**SYNON.**: Rubbing, Fr. *Frottement*, Ger. *Reibung*.

DEFINITION.—By friction we mean surface-rubbing, as distinguished from *shampooing*, or as it is sometimes called *medical rubbing*, a process of manipulation by which deep pressure is made upon the muscles.

APPLICATIONS AND USES.—Friction is usefully employed over the surface of a limb, or the trunk, for a variety of purposes. It is especially useful when the circulation is enfeebled, either by the external application of cold, amounting when in a severe degree to frost-bite, or in cases of paralysis. The effect is still further increased by the use of various stimulating liniments and embrocations, more especially when it is desirable to excite a certain amount of counter-irritation over a large cutaneous surface for the relief of congestion or inflammation of internal organs.

Another object with which friction is largely employed in medicine, is to facilitate the absorption and introduction into the system of various remedial agents applied externally, instead of being administered internally by the stomach. By this means gastric irritation and disturbance are avoided, and the effects of the remedies upon the system can be more closely watched and regulated. In this way mercury is frequently introduced into the system by the process commonly spoken of as *rubbing in*, and salivation can be more easily avoided or checked at its commencement than when mercury is administered by the mouth. The part of the body selected for this purpose is that along the inner side of the thigh up to the groin, and mercury, rubbed in, in the form of ointment, every night and morning, will generally affect the system in a few days.

Another instance of friction is to be found in the fattening of children by the process of rubbing in oil—fresh neat's-foot oil is the best—every night and morning, over the chest, abdomen, arms, and thighs. Emaciated children thus treated gain in weight by the absorption of the oil; and not only do they fatten, but their general nutrition and health are improved, often with the diminution of glandular swellings and the disappearance of cutaneous

that there is some ground for the belief in the curative influence of this method of medication in incipient phthisis. **WILLIAM ADAMS.**

FRICTION-FREMITUS.—The form of friction produced by the rubbing together of surfaces roughened by various morbid conditions, as of the pleura in breathing, or of the pericardium from the movements of the heart. See **FREMITUS**, and **PHYSICAL EXAMINATION**.

FRICTION-SOUND.—A physical sign, heard on auscultation, and due to the rubbing against each other of serous surfaces that have lost their natural smoothness and moistness from any cause. See **PHYSICAL EXAMINATION**.

FRIEDRICHSHALL, in Germany.—Sulphated waters. See **MINERAL WATERS**.

FROST-BITE.—A local effect of extreme cold upon any of the tissues of the body. See **COLD**, **Effects of Extreme or Severe**.

FUMIGATION (*fumigo*, I smother).

DEFINITION.—This is a mode of employing certain medicinal agents which are capable of being volatilized by heat, the vapour being then allowed to escape into an apartment, or to come in contact with articles of clothing and other objects, for purposes of disinfection (see **DISINFECTANT**); or being allowed to act upon the surface of the body as a whole, or upon certain parts of it, for therapeutic purposes, either local or general, on being absorbed. The chief agents which are thus used are sulphur and mercury.

MODE OF APPLICATION AND USES.—The mode of using sulphur as a disinfectant will be found sufficiently explained under the article **DISINFECTANT**. The vapour may also be brought with a therapeutic object into contact with the body or any part of it in the dry state, the sulphur being burnt in a suitable apparatus. As a general application it is used for the cure of itch, as a local application in diseases of the throat, and various other affections.

Mercurial fumigation is now commonly effected by means of the moist mercurial vapour bath, in which the skin is exposed to the fumes of mercury volatilized by heat and mixed with steam, in a suitable apparatus. This process is more effectual than dry fumigation, for the moistened skin is more capable of receiving and absorbing the mercurial vapour which settles upon it. It is not desirable to produce profuse perspiration, as this exhausts the patient, and washes the mercurial film from the body.

Various preparations of mercury have been tried, but as far as the best is calomel as recommended by Mr. Lee, which is capable of being more completely volatilized than any other form and with a less degree of heat, whilst the amount administered is more accurately known. The quantity used for each bath may be varied from 10 to 30 grains, and given daily or at such intervals as circumstances indicate. The body should be protected from cold after leaving the bath, and night is the best time for its use, as the patient can then go to bed enveloped in the cloak or blanket which has been employed in the process, and upon which much of the vapour has collected. Salivation is readily and often

quickly produced by this method, so that the gums must be carefully watched and the dose regulated. The time ordinarily required for the bath is about 20 minutes, but if headache or lassitude be caused, it must not be so prolonged.

The advantages of this practice are that mercury can be introduced into the system without giving rise to the intestinal derangements, loss of appetite, &c., which its exhibition by the mouth sometimes occasions, and its direct action upon the skin often appears to be of service. There is, however, the disadvantage that in some cases the mercurial fumes may cause a syphilitic eruption to inflame and spread.

Mercurial fumigation has been employed for primary syphilis, but it answers best in the secondary stage of the disease, and especially for the dry eruptions. Sometimes it is useful for the tertiary manifestations which resist iodide of potassium, but it should be tried very cautiously in these cases.

In certain cases where, from feeble health or other causes, it is not advisable to influence the system with mercury, the calomel vapour may be directed upon some local parts, such as an ulcerated spot. This local application has been found serviceable in treating intractable sores in advanced syphilis, in severe and obstinate ulceration of the throat, and in some other conditions.

GEO. G. GASCOYNE.

FUNCTIONAL DISEASES.—A class of diseases in which an anatomical change cannot be detected to account for their presence. See **DISEASE**, **Classification of**.

FUNGI. Diseases due to See **PARASITES**, **Diseases from**, and **MICROBIOLOGIA**, **Poisoning by**.

FUNGOID (*fungus*, a mushroom)—A term applied to superficial granulations and morbid growths, especially those of a malignant nature, when they sprout rapidly and assume an appearance somewhat like a mushroom. See **CANCER**, and **ULCERATION**.

FUNGUS-DISEASE OF INDIA.—**SYNON:** Madura foot, Mycetoma, *Morbus tuberculosus pedis*; Fr. *Dégénérescence endémique des os du pied*; Persal.

DEFINITION.—A diseased condition of the limbs and feet, occurring in India, characterized by enlargement and distortion of the affected extremity, due to thickening of the cutaneous tissues, with degeneration and subsequent fracture of the osseous structures. Two forms of the malady are described—one, the pale or albid form, characterized by the presence of minute globular fatty particles like fish-roe, and, though very rarely, by the existence of minute pink concretions not unlike red-pepper granules; the other, the melanoid or dark form, characterized by the existence of black or dark brown masses, varying in size from that of a grain of gunpowder to a walnut, and composed of fungoid filaments, cells, and pigmentary deposit.

DESCRIPTION.—This remarkable disease of the extremities does not appear to have been observed hitherto beyond the limits of Hindostan,

and has rarely been seen to affect any but the natives of that country. No case of a European or half-caste has been recorded as suffering from a typical form of the malady. The foot has been observed to be affected more often than the hand, hence it was common formerly to find the malady referred to as one peculiar to the foot. It has been recognised as a distinctive disease in India for more than thirty years, and was described by Goodfrey, of Madras, in the *Lancet* in 1846, and by Eyre in the *Indian Annals of Medical Science* in 1860. It is to Dr. Vandyke Carter, however, that we are chiefly indebted for what is known of the malady, clinically and pathologically, and his writings date as far back as 1860. His recently published memoir on the disease (*Mycetozoa, or the Fungus Disease of India*, 1874) contains a summary of all that had been written regarding it up to the period of publication. The foot or hand affected with the disease presents appearances not unlike what are observed in some of the forms of caries—especially those of scrofulous origin. When it is the foot that is affected, it is found to be considerably increased in circumference, the enlargement seldom extending far beyond the ankle, the foot is prone to run in a line with the leg, and may be everted or inverted. It is not, however, in the aspect presented by the limb that the leading peculiarity consists, but in the character of the discharges from the sinusses, the openings of which are scattered all over the surface of the affected tissue. It is this peculiarity which led Dr. Carter to separate the disease into two forms, (1) the 'pale' or 'ochroid,' the discharge of which consists of whitish-yellow rice-like bodies of about the size of millet-seed, and (2) the 'dark' or 'melanoid,' so called from the dark brown or even black granular bodies that constantly escape through the sinusses, not unlike grains of coarse gunpowder. The first form may be said to present two or three varieties, according to the modified character of the discharges: these will be referred to more definitely farther on. The malady would appear to occur more frequently in Madras, Bombay, and the more westerly and north-westerly parts of India than in Bengal proper. This, however, seems to apply more especially to the dark variety, for, whilst no well-authenticated case of this form has been recorded as having manifestly originated in the last-named province, cases of the pale variety are not infrequent. So far as the foot is concerned, the pale form is manifestly the one most commonly met with all over India, at least, if any inference may be drawn from the fact, that whilst the writers have had the opportunity of examining two or three hands affected with the

dark variety, they have not seen one affected with the pale; nor can they find any account of such a case having been witnessed. The distortion of the hand affected in this manner is very peculiar—it is shortened and thickened, owing to the destruction of the carpus and metacarpus, and the consequent irregular tension of the extensor and flexor tendons.

ANATOMICAL CHARACTERS.—On laying open a characteristic specimen of the disease, the bones are found to be extremely softened, so that they can readily be divided by means of a common knife. The interior of the hand or foot is found to be occupied by a series of sharply defined cavities, some quite isolated, but the majority communicating with one another and with the exterior by a series of complex channels or sinusses containing glairy fluid and solid concretions in various proportions. Both cavities and channels are lined by a dense, glistening membrane composed of white fibrous and elastic tissue. The surrounding tissues are generally in a very fatty condition, and, where the disease is of long standing, are more or less completely blended into an indistinguishable mass. So far a common description is applicable to both forms of the disease; but on proceeding to the consideration of the contents of the cavities, great differences present themselves.

Pale Form.—The pale or ochroid form is capable of subdivision into several varieties, according to the nature of its morbid products. In the commonest and most characteristic variety the cavities and channels contain masses of spherical bodies like fish-roe, of a pinkish-yellow or white colour, surrounded by gelatinous glairy matter. In certain cases, however, the roe-like bodies are almost or entirely absent, and the gelatinous matter and liquid oil are generally diffused throughout the tissues. In a third and very rare variety the section looks as though besprinkled with grains of red-pepper, from the presence of innumerable minute concretions of a bright red hue.

Dark Form.—The appearances presented in the dark form of the disease are strikingly different. Here, in place of the roe-like bodies of the previous form, the cavities and channels contain masses of a dark brown or black colour. These masses vary greatly in size, some not being larger than the normal fat-lobules surrounding them, others attaining to the size of a small orange. The larger masses greatly exceed any of the roe-like masses of the pale variety in size, and their consistence is also much firmer than that of the latter. They are tuberculated on the surface, and closely resemble truffles in appearance. On section, they present a more or less distinctly radiating structure, and the interior is generally somewhat lighter in colour than the tuberculated exterior coating. In some cases they are tightly fitted into the cavities in which they lie, but in others they lie loose and are surrounded by a certain amount of gelatinous matter. The amount of the latter present is, however, much less than in the pale form.

The masses of morbid material in both forms are primarily situated in spaces normally abounding in fat. Long series of them are frequently interpolated among the loculi in the

* *BREL*: Carter, H. V. *Trans. Med. & Phys. Soc. of Bombay*, 1860-62. *Trans. Path. Soc. of London* vol. xiv. 1873 (*on Mycetozoa, or the Fungus-disease of India*, London, 1874). Carter, H. Journal*, August, 1871, March, 1872. *Lewis and Cunningham, Eleventh Ann. Report of Sanitary Commissioner with the Government of India*, 1876. *Indian Annals of Med. Sc.*, vol. xviii. 1876 (Reprint). *Tilbury Fox and Parryman, In certain Endemic Skin and other Diseases of India, &c.*, 1876.

interstices, between healthy fat-lobules; others occupy the interior of the bones; and a third series are developed in the pads of fat lying around muscles and tendons. The muscles and tendons in such cases may frequently be found quite intact, although surrounded by masses of the morbid material. Due to this persistence, fracture and crushing of the softened bones often occurs, and it is on this that the distortion of the affected part is in many cases in great measure dependent.

Minute characters of the morbid products.—The rice-like particles are composed of a nucleus of granular, waxy consistence, surrounded by a fringe of radiating crystals. They appear to be almost entirely composed of fatty matter, and no traces of the presence of parasitic organisms of any kind can be detected in them. The bright red particles occurring in certain cases of the ochroid form are concretions, consisting in great part of phosphates and carbonates, and containing a considerable proportion of iron. The dark masses present in the other form of the disease are of much more complex structure. In all or almost all cases they contain septate fungoid filaments in greater or less proportion. These are sometimes difficult to distinguish, but may generally be detected by allowing portions of the material to soak for some days in liquor potassæ. The proportion which the filaments bear to the entire mass when thus separated, is in any case very small, and in some cases extremely so, for on the completion of the soaking only a very small quantity of colourless flocculi, consisting of masses of branched filaments mixed with empty cyst-like cells, is left behind in the fluid. The latter has assumed a brown colour from the solution of the dark mass. The filaments and cysts (see the accompanying figure) in so far as tests

FIG. 31.—Fungoid Filaments and Capsules obtained after prolonged maceration of the black substance in caustic potash. $\times 800$.

have yet determined, are indistinguishable from undoubted fungal elements. They are, as a rule, quite empty, and show no signs of growth, or indeed of life. The basis in which they are imbedded varies greatly in different cases. In some instances it is soft and contains much oily matter, but in the more advanced cases this is almost absent. It is then only soluble by means of alkalis. The ash consists mainly of calcium phosphate and is red, due to the presence of oxide of iron.

The fungoid filaments have never yet been

shown to be capable of any further development. All attempts at cultivation have failed in causing them to assume any form by which their true nature and relationships may be determined. They have never given any unequivocal signs of life external to the body, even when exposed to conditions favourable to the growth of fungi; as demonstrated by the development of various extraneous moulds upon the surface of the black masses themselves, or on the media in which they were immersed.

SYMPTOMS.—Dr Carter writes: 'As a rule the local indications of this disease are the same for all its forms, for commonly it is not possible to discriminate the several varieties by simple inspection or bare clinical history of the case.' The statements made by the patients as to the mode of origin and progress of these complaints are very various, but, taken generally, they seem to imply that the symptoms are analogous to those usually observed in deep-seated disease of the osseous and adjoining tissues. Eventually a more or less hard lump is felt in the sole of the foot or palm of the hand, or in several places. Generally one or more abscess-like formations occur, and ultimately several abscesses are established, the latter, as a rule, presenting a peculiar mammillated appearance—the 'tubercles,' apparently, of earlier writers. Along with these changes, enlargement and distortion of the affected member take place, but unaccompanied with severe pain. Discharges set in, more or less offensive, according to the nature of the subsequent degeneration, and the limb becomes not only useless, but a burden to its owner. In this manner the sufferer may go on for from one to fifteen or more years, unless relief be sought in a surgical operation.

PATHOLOGY.—The occurrence of the fungoid filaments in the products of the dark variety of the disease, has caused many authors to regard them as the essential cause of it. There are, however, good grounds for rejecting such a conclusion. Had the dark form of the disease been the only one with which we were acquainted, there might have been some cause to regard it as due to parasitic agency. When, however, we find that the pale form, whilst causing all the important lesions present in the other, shows a total absence of all fungoid elements in its products, we are forced to regard such elements as of secondary importance. The only means of overcoming this objection would be a demonstration that the products of the pale form are due to a degeneration of the black matter, in the course of which the fungoid elements disappear. No such demonstration has been given, and, on the contrary, it has been shown that each form is capable of running an entirely independent course, the gradual transformation of the normal fat having been traced in the one case to the production of the rice-like particles, and in the other to that of the black masses in which the fungoid elements are imbedded. Were the pale form the only one known, the disease might be described as a mere degeneration of the fatty tissue, with the results consequent on the presence of the morbid products of the process in the surrounding parts; but this explanation, although so far applicable to the dark form, throws no light on the source of

the fungoid elements. They are present in masses which are entirely isolated in the tissues, having no communication with one another or with the exterior. There is no evidence of their passage from one cavity to another—on the contrary they are absolutely limited to the contents of the cavities, the membranous walls of the latter and the intervening tissues never showing any traces of a spreading mycelium, or of any other fungoid elements.

Assuming the filaments to be of undoubted fungal origin, the facts point rather to their simultaneous and independent development in multiple centres, than to their spread from one to another. The fact of the necessity of a suitable soil or nidus, in addition to the mere presence of germs, in order to secure the development of organisms, is generally accepted. That germs of most various kinds must constantly be introduced into the blood, is a self-evident fact. Putting their introduction by means of the lungs out of the question, their constant introduction from the intestinal canal can hardly be denied. It can be demonstrated that the intestinal contents abound in vegetable organisms—spores, bacteria, &c.—in a living condition. As it is an ascertained fact that solid particles of inorganic matter of far larger size than many of these germs can enter the circulation, it can hardly be denied that the latter may, and indeed must, enter also. So long as such bodies do not meet with conditions favourable to development, they are no doubt destroyed and utilised by the living matter of the blood and other tissues. If, however, they are deposited in a medium favourable to them, they will grow and undergo such development as they are capable of. The morbid products of the disease here described are practically dead material, external and extraneous to the body, and it has been experimentally demonstrated that when removed from the body they form a basis capable of supporting the growth of fungal organisms. Given these two conditions

—the constant presence of germs in the circulation, and the possession of a suitable soil for fungi—and the difficulty of accounting for the presence of fungal elements in the latter appears in great part to disappear.

PROGNOSIS.—Both forms of the disease run a very chronic course, and often without very materially affecting the general health of the patient; in some cases, however, great emaciation accompanies the disease. With regard to the duration of the malady, it may be stated that cases have been recorded as having existed for various periods up to twenty-six and thirty years.

TREATMENT.—There are no instances recorded of a spontaneous cure having been effected, nor have remedial applications proved of material permanent value in either form of the disease. Removal of all the diseased tissue, by amputation of the affected extremity, is the only remedy which meets with general approval. The subsequent treatment resolves itself into that of an ordinary surgical operation.

D. D. CRYNINHAM.
R. R. LEWIS.

FUNGUS HÆMATODES (*fungus*, a mushroom, *alma*, blood, and *oides*, like).—A synonym for soft malignant growths, which are exuberant and highly vascular, and therefore peculiarly liable to bleed. See CANCER, and TUMORS.

FURFUR.—**SYNON.**: Scurf, Dandruff.—A bristlike desquamation of the skin, met with in several cutaneous diseases, more especially pityriasis, psoriasis, and ichthyosis. See SKIN, Dis-eases of.

FURFURACEOUS (*furfur*, bran).—A term applied to a condition in which the epidermis is shed in the form of bran-like scales. See FURFUR.

FURUNCULUS (*fervio*, I boil).—A synonym for boil. See BOIL.

G

GADFLY.—The popular name for a genus of insects whose larvæ infest man and the lower animals. See *CESTRA*.

GALACTAGOGUES (*galak*, milk, and *agogos*, I move).

DEFINITION.—Agencies which increase the secretion of the mammary gland.

ENUMERATION.—The most common galactagogues are:—Mental Emotions, Local Nervous Stimulation; Warmth, good Food, Alcohol, Jellorandi; the fresh leaves of the Castor Oil plant, Tonics; and Electricity.

ACTION.—When we consider how powerfully mental processes may affect the activity of nerves supplying the secreting structure of glands, we

can understand how these may influence the secretion of milk, as of the sweat, the saliva, and the tears. The maternal feelings of joy, as well as the reflex stimulation of the infant's lips, act most rapidly in developing the functions of the breast. Warmth and good diet also play their part in the process. Alcohol in the form of malt liquors, or malt-extract, is a useful adjunct; and so are such tonics as iron, which counteract in some measure the severe drain on the constitutional resources. Little use has yet been made in actual practice of those drugs which are specially credited with galactagogue properties; but we are told on good authority that a poultice made of the fresh leaves of the castor-oil plant, aided by teaspoonful doses of a fluid extract prepared from the

gums, have a markedly stimulating influence on the mammary secretion. Belladonna is well known to dry up the milk; and jaborandi, which is its antagonist in so many respects, has been shown to have here also a directly opposite effect, and to be a drug of which further use may yet be made when we wish to excite or re-establish the proper functions of the mammary gland.

ROBERT FANQUHARSON.

GALACTIDROSIS (γάλα, milk, and ἰδρῶς, perspiration).—A term signifying milky perspiration. See PERSPIRATION, Disorders of.

GALACTORRHOEA (γάλα, milk, and ῥέω, I flow).—An excessive flow of milk. See LACTATION, Disorders of.

GALL-BLADDER AND GALL-DUCTS. Diseases of.—These affections may be considered in the following order:—

1. **Catarrh of the Bile-passages.**—This disease very rarely gives opportunity for examination after death. At the time after death that it is customary to make post-mortem examinations in this country, all redness of the duct has usually disappeared, and there are left only swelling and pallor of the mucous membrane which is covered with a tenacious glassy or purulent secretion. By this swelling and secretion, the bore of the duct is often greatly narrowed; and it can be seen that no bile has passed over it for some days, as all colour has disappeared from the affected part of the tube. In judging of this, however, no pressure must have been made upon the gall-bladder during the earlier part of the examination. These appearances are most pronounced in the common duct and the gall-bladder, they are gradually lost in the hepatic duct and its branches in the liver. The process seems most intense at the duodenal end of the gall-duct, and the orifice of the papilla itself is often found plugged by mucus, an appearance which certainly favours the notion that the catarrh is propagated from the stomach and duodenum. This is believed to be the commonest source of catarrh of the bile-ducts. It is also seen in nutmeg-liver and cirrhosis, and a tendency to chronic catarrh is set up by the presence of foreign bodies in the ducts, such as gall-stones.

Symptoms.—Jaundice is often the first symptom which draws the attention of the patient to his health in a case of catarrh of the bile-ducts, although in a certain number of cases this is preceded by symptoms of gastric disorder, such as vomiting or sense of sickness, loss of appetite, and furred tongue; or, on the other hand, by diarrhoea. The jaundice lasts about three weeks, sometimes as much as six or eight weeks. After this, suspicion should be aroused whether something more than a simple catarrh be not present.

Differential Diagnosis.—The diagnosis depends upon the absence of any physical signs indicating organic change in the liver; and on the presence of gastric symptoms. Thus nearly all cases of simple jaundice are diagnosed by some physicians as cases of catarrh of the bile-ducts. As the greater number of the patients recover, very few opportunities are given for verifying this diagnosis; but in those which have been

examined, plugs of mucus in the ducts have not unfrequently been found. The catarrh caused by gall-stones is lost in the jaundice and pain associated therewith.

TREATMENT.—The treatment should at first be directed to the gastric symptoms, beginning with a purgative, followed by a course of efferevcesc alkaline medicines, and restricted diet. Later on, dilute nitro hydrochloric acid taken before meals is often very useful.

2. **Inflammation and its Results.**—In some cases of typhus and typhoid fever, and in other typhoid states, the gall-ducts and gall-bladder become ulcerated, or filled with purulent fluid, or covered with *crustacea exudativa*. The same thing may happen when gall-stones are impacted in the ducts. The gall-ducts are sometimes obliterated by fibrous bands passing over them. Sometimes they suffer a congenital obliteration by the overgrowth of the fibrous tissue around them.

3. **Dilatation.**—The gall-ducts and gall-bladder become dilated whenever there exists an obstruction either pressing on the ducts from the outside, or formed within them. The first result is dilatation of the ducts behind the obstruction. The gall-bladder becomes much dilated, often filled with a thick green bile. If the obstruction last long, the coloured part of the bile is absorbed, and its place taken by a colourless fluid, either viscid or limpid. This fluid contains neither bile-pigment nor bile-acids, is often albuminous, and contains abundance of mucus. The ducts outside the liver may be enormously distended. It is common to see them as big as the middle finger. Within the liver they are also dilated, but not to so great a degree, and they are more dilated on the left than on the right side. The dilatation of the ducts may become cystic, and sometimes tumiform. The writer has always been able to find columnar epithelium in these dilated ducts. In some cases of long-continued obstruction, the contents of the bile-ducts become colourless; in other cases, purulent; and small abscesses form around the bile-ducts, and open into them. These abscesses may be multiple; or, more commonly, only a single large one is formed. The abscess or the dilated gall ducts may rupture into the peritoneum, and cause fatal peritonitis.

4. **Cancer.**—Primary cancer of the gall-ducts and gall-bladder is sometimes met with; or they may be affected secondarily.

5. **Foreign bodies** are occasionally met with in the gall-ducts. The most common of all are, of course, *gall-stones*. Much less common are entozoa, such as the *Distoma hepaticum*, *hydatids*, or the two kinds of *ascarides*.

Symptoms.—In all these different morbid states, it is usually only possible to say at the bedside that the large bile-ducts are obstructed; a more complete diagnosis is commonly impossible. Jaundice is an important symptom, as without it disease of the bile-ducts cannot be diagnosed. It is commonly very intense, the urine being deeply coloured, and the feces quite colourless. The enlargement of the liver, if present, is commonly uniform, the surface being smooth, and the edges well-defined. The gall-bladder may often be felt at the edge of the right lobe as a rounded tumour; this is

then a sure sign of the obstruction of the gall-ducts. In simple diseases of the gall-ducts there is an absence of splenic tumour, of ascites, and of other symptoms of portal obstruction. In many cases, however, diseases of the liver and of the gall-ducts are so intimately bound up together, that they cannot, during life, be separated.

Prognosis.—The prognosis, if simple catarrh of the gall-ducts and gall-stones can be excluded, is unfavourable.

Treatment.—The treatment must be conducted on general principles.

6. Enlargement of the Gall-bladder.

The gall-bladder cannot be felt in health during life. But it may often readily enough be made out where there exists any obstruction in the common or cystic duct, so that it becomes distended with fluid. It may also be felt when the walls become fibrous or calcified, or the seat of cancer; or when its cavity is filled with gall-stones. A tumour may then be felt under the border of the right lobe of the liver, in the situation of the gall-bladder. When filled with fluid, a rounded, sometimes oblong, sometimes pear-shaped tumour is felt; in other cases it has an irregular shape, or a somewhat rounded outline. A greatly-distended gall-bladder has been mistaken for ascites, and tapped. The diagnosis depends chiefly on the situation of the swelling, and even then the distended gall-bladder may be mistaken for hydatid-disease of the liver-substance or of the omentum, or for a tumour of a neighbouring organ which has pressed against the liver. The difficulty of the diagnosis is much increased if the liver be moved from its natural place, for then the position of the gall-bladder becomes uncertain. Bamberger says he has often mistaken a softened cancerous nodule of the liver for a distended gall-bladder. If it be certain that a fluctuating tumour be the gall-bladder, and no jaundice be present a diagnosis may safely be made of hydrops cystidis felleae, or dropsy of the gall-bladder; but if jaundice be present, or if the tumour do not fluctuate but appear solid, there are then no definite rules for diagnosis; all depends upon the surrounding facts of the case. Dropsy of the gall-bladder is not a dangerous disorder, and requires no treatment; while the prognosis and treatment of the other states depend entirely on their respective causes.

7. Perforation.—Perforation of the gall-bladder or of the gall-ducts is generally the result of ulceration, due to gall-stones, inflammation, and other causes. Fatal peritonitis ensues if the perforation occur into the abdominal cavity. Frequently, however, previous adhesions have been formed between the biliary reservoir or duct, and the neighbouring organs or the abdominal wall, and the result of this is—

8 Biliary Fistula.—This may exist between the gall-bladder or gall-ducts and the surface of the body, the stomach, colon, or duodenum. Very rarely gall-stones find their way into the urinary tract. J. WICKHAM LEAG.

GALL-STONES.—SYNON: Hepatic Calculi; Cholelithiasis; Fr. *Calculs biliaires*; Ger. *Gallensteine*.

Description.—Gall-stones are seen in man and

most of the vertebrate animals, and in some molluscs. They are especially common in cows. They are found in the biliary passages; most usually in the gall-bladder, or the cystic and common duct; more rarely in the hepatic duct, and in its branches within the liver. They vary in size from fine gravel to concretions five inches long. The largest are commonly single, and then they are rounded or oval in shape. The smaller calculi are usually numerous, being then tetrahedral or wedge-shaped, showing the facets or plane surfaces caused by mutual pressure. They are never lighter than water when first removed from the body. Only after drying do they float. Their consistence when raised to the ordinary temperature of the body becomes much less, so that they can be moulded by the fingers. Their colour varies from white to almost black; most commonly it is brown.

Dr Thudichum thinks that the nuclei of gall-stones are mostly formed of casts of the hepatic ducts. There is rarely more than one nucleus. Its chemical composition is a compound of lime and bile pigment, or traces of mucus and phosphatic earths. The chief chemical constituent of human gall-stones is cholesterol; some gall-stones are wholly composed of this substance; most contain 70 or 80 per cent. Other constituents of gall-stones are the bile-pigments, either by themselves, or in combination with lime. Very small quantities of the bile-acids are found, and these are also in combination with lime. It is rare to find gall-stones with any large amounts of carbonate or phosphate of lime, though the ash of nearly all gall-stones shows a large amount of carbonate of lime, the product of the combustion. Traces of copper, iron, and manganese are found in nearly all gall-stones. Lime-salts of the fatty acids are likewise found.

Ætiology.—Age has a very great influence in the production of gall-stones; they are exceedingly rare in infancy and childhood, their frequency increases after the age of puberty, and they become still more common after thirty. Women are thought to be more liable than men to gall-stones. In cancer of the liver, gall-stones are certainly very commonly found, while on the other hand in cirrhosis they are scarcely ever seen. Want of physical exercise and indigence in rich diet seem to favour their production.

Pathology.—What is the cause of the first formation of a gall-stone? It is not simply concentration of the bile, since the cholesterol and pigment remain in solution so long as the bile is unchanged, but the beginning of decomposition of the bile-acids causes a precipitation. The cholesterol is likewise thrown down when the reaction of the bile changes from alkaline to acid. Gorup-Besanez and Dr. Thudichum have kept bile several months, and found the reaction at the end of that time acid, with an abundant sediment. It is thus probable that the retention of bile in the gall-bladder or gall-ducts favours the growth of these concretions. It is also probable that gall-stones are sometimes dissolved spontaneously, as erosions may sometimes be seen on them; or they may break up, and thus pass out.

Symptoms.—Gall-stones while still in the gall-bladder rarely give any signs of their

pathology. They are frequently found in the gall-bladders of persons who during life had no symptoms which could be referred to the liver. It is when they begin to leave the gall-bladder, and escape into the cystic and common duct, that symptoms arise of gall-stone colic. They often begin with a dull pain near the liver, with vomiting, rigors, and elevation of temperature, or, quite suddenly, a severe pain in the right hypochondrium comes on, described as shooting, stabbing, burning, &c. The pain extends into the epigastrium, rarely to the left hypochondrium, to the right shoulder, and, according to some, even into the extremities. The pain is very intense, and may give rise to delirium and convulsions in nervous persons, or to hysterical attacks in women. Vomiting is usually present, and, as the attacks most often come on after eating, at first only the food taken is thrown up, and then a colourless mucus. The right hypochondrium is usually very tender, and the muscles are rigid. The pulse is not increased in frequency, being indeed rather below than above the natural number. In violent attacks the pulse becomes very frequent and small, or almost imperceptible, the eyes are surrounded with dark marks, the nose is pointed, the breath is cool, and cold sweats break out over the body. In this state death may occur but it is a rare event. A few hours after the attack, the conjunctivæ may show a yellow tinge, which will gradually spread from the upper part of the trunk all over the body. The jaundice is more or less intense according to the shape of the gall-stone—whether completely obstructing the duct, or merely causing a hindrance to the passage of the bile. In some cases jaundice may be altogether wanting, as when the stone is in the cystic duct. The jaundice may last an indefinite time. The duration of the attack of colic itself varies, usually not lasting more than a few hours, it may extend over several days. As soon as the gall-stone reaches the duodenum the attacks are over, the stools become dark, and the jaundice begins to disappear. When the gall-stones reach the intestine, they are commonly evacuated with the feces; some cases have, however, been recorded in which they were so large that symptoms of intestinal obstruction were caused and death resulted.

DIAGNOSIS.—The diagnosis of gall-stones is often more or less difficult. Some physicians think that the diagnosis should not be made unless the concretions be found in the stools; and the search for them should be made by passing the fingers through a sieve. It is agreed by nearly all that it cannot be made if there be no jaundice present. Cancer of the head of the pancreas may readily be mistaken for gall-stones in the common duct.

PROGNOSIS.—It is almost impossible to make a trustworthy prognosis in these cases. The physician can never speak confidently or feel quite happy when treating a case which he looks upon as one of gall-stones.

TREATMENT.—The treatment of gall-stones may be discussed under two heads: during the paroxysm of the colic; and between the attacks.

During the paroxysm, the great object of the physician is to relieve the pain. This may best

be done by full doses of morphia; and if this be rejected by vomiting, it may be administered hypodermically. The patient may be put in a warm bath and kept there, the heat being maintained by the renewal of the warm water. Should these means fail, chloroform or ether may be inhaled.

Between the attacks of biliary colic a great number of remedies have been proposed: the most popular is Darwin's, which consists of three parts of ether and two parts of turpentine: the best plan is to give 10 to 20 minims of this mixture three times a day, enclosed in capsules or pearls. The German physicians have great confidence in the alkaline mineral waters, especially Carlsbad. Some think this due simply to the large amount of water daily ingested, causing a large flow of bile. Others recommend purgatives, as castor oil or turpentine; or aqua regia. Emetics have been employed, but they are dangerous on account of the straining which they cause, and which may lead to the rupture of a vessel.

GALLOPING CONSUMPTION—A popular name for phthisis when it runs an acute or rapid course. See PHTHISIS.

GALVANISM, Uses of. See ELECTRICITY.

GANGLION (γάγγλιον, a hard gathering). This term is applied to a variety of somewhat different affections, including—1. The *simple* ganglion. This is a cystic tumour formed in connection with the sheath of a tendon. 2. The *compound* or *diffuse* ganglion, which consists of a chronic effusion into the common sheath of a group of tendons, giving rise to a fluctuating swelling. One variety of this contains the so-called melon-seed bodies. 3. The term is extended by some writers to enlargements of the larynx mucosæ. See BRUISES Diseases of.

1. **Simple Ganglion.**—**DEFINITION.**—The simple ganglion forms a rounded tumour, occasionally lobulated, situated in the immediate neighbourhood of some tendon. The most common situations are the dorsum of the hand, the dorsum of the foot, the palm of the hand at the root of a finger, and behind the outer or inner malleolus. The tumour varies in size from a pea to a pigeon's egg. It may fluctuate distinctly, or be so tense as to seem absolutely solid. It is not adherent to the skin or to the tendon with which it is in relation. It is painless, but often gives rise to a sense of weakness in the affected part. The wall is composed of a more or less delicate fibrous tissue, lined with the surrounding areolar tissue, and lined by an imperfect layer of endothelial cells. Its contents are most usually semi-solid, like apple-jelly, but sometimes fluid. They are said to be neither albuminous nor gelatinous, but colloidal in character. As to the exact nature of the tumour, opinions differ, and probably it is not always the same. It is said to arise in the following ways: 1st, by a hernial protrusion from the sheath of a tendon, the neck of which becomes gradually contracted and finally closed, so giving rise to a cyst in intimate connection with the sheath. 2nd, Gosselin has described small follicles or sub-synovial crypts, which he believes may become dilated, so as to

form ganglion. **Sol.** The tumour may be a cyst or entirely new formation.

TREATMENT.—Painting with iodine is of little or no use. Forcible rupture of the cyst by a blow or pressure sometimes effects a cure; but the best treatment is to puncture the tumour with a clean grooved needle, and to squeeze out the contents, afterwards applying pressure or a blister over the collapsed cyst. This treatment may require to be repeated more than once.

Compound or Diffuse Ganglion.—**DESCRIPTION.**—This disease is almost exclusively confined to the sheath of the common flexors of the fingers. It may consist of a simple dropsy of this sheath, forming an hour-glass-shaped swelling in the front of the wrist, the constriction being caused by the annular ligament; or, in other cases, the tumour may contain melon-seed bodies, which give rise to a sense of soft crackling when it is manipulated. These melon-seed bodies are smooth, oval and flatish in shape, and of a pearly-white colour. They are of almost cartilaginous toughness, and on section present an appearance of concentric lamination. Under the microscope they are found to be composed of very imperfect fibrous tissue. Their origin is somewhat doubtful. They have been supposed to be due, first, to hypertrophy of the fringes, normally found on a synovial membrane, the pedunculated projections so formed being ultimately broken loose by the movement of the tendons; secondly, to the formation of pedunculated warty outgrowths on the synovial membrane, which become free in the same way; thirdly, to fibrinous deposits taking place from the fluid in the ganglion; and, fourthly, to the results of accidental hæmorrhage. When these bodies are abundant, the fluid is usually scanty.

Ætiology.—The cause of this affection is uncertain, but it must be remembered that in many cases it is due to the irritation caused by the earliest stage of disease of the carpus.

TREATMENT.—The treatment of compound ganglion is unsatisfactory. Iodine is useless. Aspiration followed by the injection of iodine has occasionally been of service. An incision made into each end of the tumour, followed by drainage under antiseptic dressing, is often of use. In extreme cases syne recommended laying the whole cyst open, and allowing it to granulate. This always left much stiffness in the tendons. When melon seed bodies are present, they must be removed by incision, and the case treated antiseptically. **MACLEA BLACK.**

GANGLIONIC NERVOUS SYSTEM, Diseases of. See **SYMPATHETIC NERVE, Diseases of.**

GANGRENE (*γᾱλρῆ*, I corrode)—**SYNON:** Mortification; Sphacelus; Fr. *Gangrène*, Ger. *der Brand*.

DEFINITION.—Gangrene is the arrest of the functions of organic life in a circumscribed portion of the soft parts of the body, leading to the complete death of the same.

The whole process of death is included under the term gangrene—the result being mortification, or necrosis of the invaded tissue, organ, or limb.

CLASSIFICATION.—*Clinically*, gangrene varies greatly according to its position, cause, extent, the powers of the patient, and the existence of complications. The disease may also be classified *etiotogically* and *pathologically*, into *spontaneous* or *traumatic*, *dry* or *moist*, *chronic* or *acute*, *gangrene, senile gangrene*, and *hospital gangrene*. The division into dry and moist gangrene, although convenient, has little pathological significance, being founded on physical characters. Both dry and moist gangrene may arise from similar causes, and coexist even, in different parts of the invaded structures, and it cannot always be predetermined whether a gangrene shall be of the dry or of the moist form. Dry gangrene is usually dependent on senile changes, limited in extent, and chronic in progress; the parts first affected having time to dry up as the disease invades those adjacent and becoming mummified, hard, and black, resembling the knuckle of a Spanish ham. Moist gangrene occurs when a larger area of living tissue suddenly mortifies, and especially if it have been previously inflamed or gorged with blood, the dead parts becoming rapidly transformed into a deliquescent putrid mass, infiltrated with gas. To this type belong many different forms of gangrene, for instance, that following the obliteration of the main artery of a limb by a ligature, or its becoming plugged by an embolus, or the form called *spreading traumatic gangrene*, or gangrene affecting an internal organ.

Ætiology.—The causes of gangrene may be local, constitutional, or a combination of both. Amongst local causes we find intense inflammation of some organ or tissue, such as pneumonia, noma, cellulitis, anthrax, or phlegmonous erysipelas. Injuries and mechanical violence of various kinds, and extremes of heat or cold, as seen in burns and scalds or in frostbite, also lead to gangrene. Gangrene may be produced either as the direct consequence of the long-continued application of cold, or as the result of the subsequent inflammatory reaction. Local arrest of the circulation, as in a strangulated hernia, an intussusception, or internal strangulation, a ligatured hemorrhoid, a too tightly bandaged limb, or severe paraphimosis, may lead to gangrene. It may also occur from extravasation of urine or sweat. Continued pressure produces a variety of gangrene called *bedsores*, especially in lowly vitallized parts, and in persons suffering from chronic diseases, or from certain lesions of the nervous centres. See **ULCER** and **ULCERATION**.

One of the most frequent constitutional or general causes of gangrene is deficient blood-supply, dependent upon disease of the arteries and heart, the result usually of systemic decay, whence the term *senile gangrene*. Gangrene may occur in the course of certain severe diseases, as diabetes, typhus, typhoid, measles, and scarlatina, embolism being in many cases the immediate cause of the complication. The gangrene due to ergotism is probably induced by the effect of the poison on the blood-vessels. A peculiar form of gangrene sometimes met with in the extremities—the *gangrène symétrique* of the French, is one in which no more definite cause can be found than anæmia, and an extremely feeble circulation. And, finally, there is *hospital gangrene*—

gangræna d'hôpital, a disease seldom met with now except amongst wounded soldiers accumulated in great numbers in foul hospitals near a battle-field.

Symptoms.—The symptoms of gangrene vary with the species, the extent, and the stages of the disease, and with the rapidity of its progress; and also according as it is dry or moist, incipient or complete. The importance of the tissue or organ invaded, and the presence or absence of complications, such as renal or cardiac disease, or of fever, also create differences.

The earliest symptoms are those of diminished circulation, sensibility, and temperature, together with change of colour in the part affected. Pain is one of the primary symptoms, and often precedes the others. In dry, senile, or chronic gangrene, there may in some cases be few symptoms beyond moderate local pain and discomfort, though oftentimes the pain is intense, whilst, when the type is of the moist or acute variety, the symptoms are usually more severe, and have a tendency to lapse into those called the typhoid or septicæmic. Between these two forms there is every intermediate grade of severity. The amount of fever varies at the onset, but it is usually considerable. The patient generally suffers much from pain, restlessness, and want of sleep; the appetite is bad; the tongue is loaded; and the pulse is feeble or intermittent. When the disease becomes arrested, the dead portion of tissue slowly separates and drops off, or is removed; very often, however, the disease steadily progresses, and the patient dies from exhaustion, or more rapidly from the absorption of septic matter.

Such being the principal symptoms of gangrene in general, we may next describe the symptoms of the leading varieties of the disease.

Dry or Chronic Senile Gangrene.—In the dry form of senile gangrene the part is gradually starved to death. The disease generally occurs in the toes, very rarely in the fingers; and is either spontaneous or excited by some trivial cause. A discoloured patch appears on one of the toes, of a dusky reddish-brown colour, which soon becomes dry and black in the centre. The disease spreads very slowly to the adjacent parts. First, a zone of discoloration appears from the blood stagnating in them; then they become livid, red, and inflamed; afterwards darker; and, finally, black and dry. One or several toes may be involved, or the foot in whole or in part. The patient generally dies sooner or later, exhausted by pain, and from general feebleness of the vital powers. Sometimes a line of demarcation appears, the dead parts separate, and recovery follows; but as a rule relapses take place.

Moist or Acute Senile Gangrene.—This form of senile gangrene is more active in its progress, and more rapidly fatal. It is often ascribed to some slight local irritation or injury, such as an inflamed corn or nail. The affected toe becomes dusky-red, swollen, and extremely painful; soon after the dark hue of absolutely dead tissue appears, following closely the zone of inflammation; and this gradually spreads onwards till the whole foot or possibly the leg, if the patient survive, becomes implicated. Beyond the gangrenous area the skin is mottled, and presents all

the appearances due to impeded circulation. In this type of gangrene, stasis of the blood and coagulation first take place in the capillaries, and extend thence to the smaller arteries. It occurs in elderly persons with feeble circulation, due to fatty heart and atheromatous arteries.

Gangrene from Arterial Obstruction.—The most common form of moist gangrene is that due to sudden arterial obstruction—when the collateral supply cannot establish itself with sufficient rapidity. It is acute, and a large part of the body being at once gangrened, the tissues do not, as in dry gangrene, have time to densitate *part passim* with the spread of the disease. It may happen after ligation of a main trunk for aneurism, or by the formation of a fibrous clot upon the roughened wall of an atheromatous vessel, and consequent plugging, or by embolism of some artery. An entire limb may thus be lost. Venous obstruction *per se* does not produce gangrene. In cases due to embolism—a form rare in the upper limbs, but common in the lower extremities, and more especially in the anterior tibial arteries—sudden and severe pain marks the onset of the disease. The temperature of the part rapidly falls, livid discoloration and loss of sensibility ensue, the veins if emptied fill very slowly, the skin mottles, bullæ form filled with turbid fluid, the colour changes from whitish grey to green, olive, or black; and the affected tissue at length becomes a deliquescent putrid mass, often crepitating from gas imprisoned in the meshes of the cellular tissue. The tendons, blood-vessels, and nerves resist the disintegrating process longest.

Gangrene from Inflammation.—Gangrene as the result of intense inflammation is likewise of the moist type. When it supervenes, the tension, pain, and swelling of the inflamed area subside, the part becomes soft and puffy; the colour changes into dusky violet, brown, or black; and all the evidences of rapid decomposition, varying with the part affected, and the acuteness of the inflammation, make their appearance.

Gangrene as a Complication of General Disease.—Gangrene is occasionally met with in the later stages of typhoid fever, or even during convalescence; and usually occurs in the lower limbs, though sometimes in the lungs, or face. It is of vascular origin, and is a most grave complication. In form it may be either dry or moist, and may be of either of two kinds. One is of early occurrence in the progress of the disease, and generally affects the toes symmetrically, the other occurs later, or during convalescence, and is of embolic origin.

Mucules is prone in some cases to occasion gangrene, generally affecting the face, the vulva, or the lungs. Scarlatina and some forms of erysipelas are also occasionally followed by extensive gangrene. The disease has been also observed during some epidemics of cholera. Gangrene produced by the prolonged consumption of diseased rye-bread chiefly occurs in the male adult, and very rarely in women or children. Other symptoms of ergotism will then be present, gangrene being a late occurrence. Gangrene from ergotism precisely resembles ordinary senile gangrene. It almost invariably appears in the lower limbs; and when a line of demarcation

forms this generally seems to correspond with the nearest joint. In diabetic gangrene no special vascular deficiency can be traced. The vitality of the tissues seems impaired by the glycosuric condition, and some slight accidental cause provokes a gangrenous inflammation.

Hospital Gangrene.—Hospital gangrene presupposes a wound: the lesion on invasion, ceases to discharge, and becomes covered with a grey tenacious slough extending from the centre towards the edges, which become much inflamed and crusted. The patient rapidly lapses into a typhoid condition; and the issue is generally fatal.

Acute Traumatic or Spreading Gangrene.—This form also follows upon an injury, which may be either slight or severe. It is generally seen in one of the extremities, originating in a wound and rapidly spreading towards the trunk—*Gangrene foudroyante*. It is in many cases intimately associated with, and probably induced by, septic infection of the system. It is usually fatal, and scarcely amenable to treatment.

Visceral Gangrene.—The gangrene of internal organs will be found described in connection with the diseases of the several organs.

Prognosis.—The progress of gangrene dependent on constitutional causes is too often from bad to worse; and a fatal issue may supervene without any attempt at repair. The gangrenous inflammation, preceding the actual death of the part, continually invades fresh tissues, the fever increases; a sallow sunken countenance, with rapid thready pulse, sordes, muttering delirium, tympanites, hiccough, sibilantus, scanty loaded urine or even suppression, supervene; the weakness increases, and death, preceded by collapse, takes place.

In other cases, especially those dependent on local causes, there is a tendency to limitation, and the process by which this is accomplished is the same for all kinds of gangrene, in every part of the body. In superficial structures a red band of healthy inflammation will be observed at the junction of the living with the dead part, called the *line of demarcation*; active cell-infiltration takes place, and a separating wall of fibrin and young cells is established in the layer of living tissue nearest to the dead structures. This becomes by degrees converted into an ordinary granulating surface, and the dead tissue is detached and cast off. The time required for this separation varies with the bulk of the dead portion, the nature of the tissue, and the vitality of the individual. The risk of septicæmic poisoning is present throughout the entire course of the disease.

Diagnosis.—The diagnosis of gangrene of external parts cannot be attended with any difficulty; the evidence of its presence being readily appreciated when the symptoms already described make their appearance.

Prognosis.—The prognosis of a case of gangrene will mainly depend on the likelihood of the disease becoming limited, the strength of the patient, and the conditions in which he is placed; which are all at first difficult to determine. The cause of the gangrene, and the presence or absence of organic mischief elsewhere, also exercises a great influence. When the malady is dependent on a constitutional cause, there will be little tendency to delimitation, and a bad pro-

spect of recovery. When the cause is local, and the destruction of tissue neither extensive nor invading a vital part, the prognosis will be favourable. But a local injury, when the conditions are unfavourable, may be followed by a severe and extensive gangrene, or some essential part of the body may become implicated.

Treatment.—When gangrene is imminent, our first care should be to adopt means to support the vital warmth of the part, and to encourage and relieve the embarrassed circulation. When the disease is fully developed, our attention must be directed to control as far as practicable the spread of the disease: to favour the separation of the dead tissue; and to keep the parts as clean and harmless as possible. We must also anticipate complications, or combat them when they occur, and support the patient's strength by good food, stimulants, and fresh air, together with opiates sufficient to allay pain. A limited traumatic gangrene is to be treated as an ordinary sloughing wound. If a complete portion of a limb be involved amputation should be performed, as soon as the line of demarcation is established. In gangrene due to arterial obstruction the extremity should be raised to assist the return of venous blood; antiseptic dressings and cotton-wool applied locally; and plenty of bland food administered at frequent intervals. When the whole limb is affected, nature may be assisted by completing the amputation of the part as soon as the limiting line is distinct. In gangrene caused by the ligature or rupture of a main artery, or the pressure of an aneurism, amputation close to the seat of the lesion may at once be performed, as the gangrene cannot extend higher than this point, but even under these circumstances it will often be safer to await indications of a commencing demarcation and then to amputate close to it. In spreading traumatic gangrene early amputation of the affected limb has been strongly recommended; but as this cannot remove the already poisoned condition of the blood, upon which in all probability the gangrene depends, it is clearly a useless measure, as the gangrenous action would invade the stump. In cases where traumatic gangrene is localized and dependent merely upon the violence of the injury, the vitality of the individual will be sufficient to overcome the mischief, unless it be very extensive. A line of demarcation will appear, and then, but not before, will it be proper to amputate, unless the part be otherwise hopelessly injured, or a large articulation opened, when immediate amputation is indicated. For the treatment of gangrene occurring in internal organs the reader is referred to the articles on diseases of the several viscera.

WILLIAM MAC CORNAC.

GARGLE (*γάργας*, I wash the throat).—

SYNON.: Fr. *Gargarisme*; Ger. *Gargelmittel*.

DEFINITION.—Gargles are employed for the production of local effects on the throat and pharynx.

MODE OF GARGLING.—This consists in taking about a table-spoonful, more or less, of the gargle into the mouth, throwing back the head, and agitating the liquid by the air expelled through the larynx. With some persons the gargle goes

M M

little beyond the uvula and base of the tongue; but if the head be thrown well back, the fluid can be made to pass into the cavity of the pharynx, and may even reach the larynx and vocal cords. The tension of the muscles, in thus throwing back the head, is apt to provoke efforts at deglutition, so that sometimes small portions of the gurgie may be swallowed; and occasionally the effort terminates abruptly in the patient jerking his head forwards, and expelling the gurgie forcibly through the nose.

Dr. H. Guinier of Cauntera has demonstrated a method of gargling the laryngeal cavity. His instructions are as follows — 1. Slightly to raise the head; 2. To open the mouth moderately; 3. To protrude the chin and lower jaw; 4. To emit the sound of the double vowel *a*. These four movements open largely the back of the mouth, lift the velum palati and uvula, separate the base of the tongue from the posterior wall, and allow the liquid used for gargling to gravitate into the cavity of the larynx. One expiratory act is the only respiratory movement that is now possible, deglutition is under control, and the gurgie bathes the pharynx and supraglottic portion of the larynx.

Uses and Composition.—The use of gargles is contra-indicated in parenchymatous inflammations of the tonsils, and in all cases where movement of the fauces causes severe pain, and where, as in some persons, an inability exists to retain liquid beyond the anterior pillars of the fauces, for these it is more convenient to apply the fluid to the fauces and pharynx, either by injection, or in the form of a medicated spray, or else by aid of a brush or sponge.

Gargles vary in composition according to their object. If prescribed with the view of exercising the muscles of the soft palate and pharynx, and thereby increasing their tone, cold or lead water is generally sufficient. If with the view of reducing and allaying local inflammatory conditions of the throat, solutions of chlorate or nitrate of potash or of borax (two drachms to eight ounces), or of liquor ammoniac acetatis (one part in four), combined with decoctum lini compositum, thin gruel, or water, and used warm, are the best. When it is desirable to excite the mucous membrane and neighbouring glands to further secretion, and thus reduce local congestion, stimulant gargles are useful, such as the tinctures of cayenne (half-drachm to eight ounces), arnica, myrrh, pyrethrum, and eucalyptus rostrata (two drachms to eight ounces); this class of gargles often relieving the deafness caused by obstruction of the Eustachian tubes, by increasing the pharyngeal secretion. To check excessive secretion astringents, in the form of the salts of iron and zinc, iron-alum, or alum (sixty grains to eight ounces), tannin (half-drachm to eight ounces), or rhubarb infusion, are advisable. If we require to check ulceration, or to dilute and purify foul or putrid secretions from the throat and tonsils, antiseptic gargles, composed of the solutions of permanganate of potash (two drachms to half-a-pint), of chlorinated soda (one drachm to eight ounces), of sulphurous acid (one part in four), or of glycerine of carbolic acid (half-ounce to eight ounces), will answer the purpose. In cases of syphilitic sore-throat, a gargle of perchloride

of mercury (three grains to eight ounces) has been recommended. In many cases combinations of different kinds of gargles are beneficial. Water, barley-water, rose or orange-flower-water, sweetened with a little honey, glycerine, or syrup, constitute the bases of most gargles.

GASTRIN, in the Austrian Alps. Simple thermal waters. See MINERAL WATERS.

GASTRALGIA (γαστήρ, the stomach, and ἄλγος, pain)—SYNON.: Gastrodynía, Fr. *Gastralgie*, Ger. *Magenschmerz*.

DEFINITION—Pain in the stomach, which occurs in various gastric disorders, and which, considered by itself, is not much to be relied on as a sign of disease.

SYMPTOMS.—In acute erythematous gastritis a burning, painful sensation affecting the stomach, and not infrequently extending up the œsophagus, is felt almost immediately after taking food or a stimulant liquid. In acute catarrhal gastritis pain is seldom complained of. In ordinary chronic gastritis it is usually absent, or, at most, only a slight heaviness or fulness after food forms a symptom of the malady. In what the writer has named 'eczema of the stomach' the pain is very severe, comes on two or three hours after food, and is temporarily relieved by eating. The same kind of pain may be observed whenever there is profuse mucous secretion, but it is less severe than in cases where gastric disturbance replaces eruptions of the skin. The pain accompanying pyrosis is of a spasmodic character, and is relieved by the ejection of a tasteless fluid. Severe pain is a common accompaniment of atonic dyspepsia, occurring in nervous or hysterical persons. It comes on when the stomach is empty, but is often aggravated directly after food, and is relieved by the escape of flatus, and by stimulants. The most severe gastralgia is that accompanying ulceration of the stomach. In this disorder it is referred to one spot, and is likewise often felt in the back. The mere fact that a pain in the epigastric region is confined to one small spot should induce the practitioner to view the case with suspicion. The pain in ulceration is usually absent when the stomach is empty, but comes on from two to ten minutes after food. In other instances a longer period, such as half an hour, elapses; but it is this definite relation to the digestive process that makes the pain of ulceration characteristic of the disease. It is usually said that when the pain comes on directly after food the cardiac region is the seat of the ulcer, and where a longer interval takes place the sore will be found near the pylorus. This, if true as a general rule, is, nevertheless, open to many exceptions; for, as a patient observed, the pain occurred later after taking food in proportion as she improved in health, and the first evidence of a relapse was the shortness of the interval of ease after eating. In cancer the pain is more continuous than in simple ulcer; it is less influenced by the digestive process, and is more diffused. It is, however, no uncommon circumstance to find cancer of the stomach without any complaint of pain. The softer kinds of malignant growth seem to the writer least apt to

cause suffering, probably because the peritoneum is less liable in such cases, than in the other forms, to be affected with inflammatory action. Neuralgia of the stomach is a favourite disease with some authors. There is no doubt that the normal sensibility of the stomach is vastly exaggerated under some conditions, but the writer's observation leads him to believe that neuralgic pain affecting the stomach, *independently of other disease*, is a much rarer complaint than is generally supposed (see STOMACH, Diseases of). The writer has met with three different forms of pain in the region of the stomach ascribed to neuralgia, which are evidently of a different nature—1. Where severe pain has come on at some period of the day at a certain hour, at a considerable period after the commencement of digestion. In many of these cases it has been evident on inquiry that the apparent periodicity was the result of the punctual disposal of the chief meal of the day. They were, in fact, cases of chronic catarrhal gastritis attended with considerable secretion; most of them occurred in gouty men, and might be classed under the head of eczema, rather than of neuralgia of the stomach. 2. Cases such as the following:—A young lady had suffered for many months from agonising pain in the left hypochondrium, coming on at each menstrual period, and resisting all methods of treatment. In this and other similar cases, it will be found that the seat of the pain is really external, in the intercostal nerve, and not in the stomach itself. 3. Severe attacks of pain in the left hypochondrium and epigastrium in females of a nervous temperament, who had either been born, or had passed most of their lives, in tropical countries. The real seat of the pain in such cases appears to be the colon, there is always constipation, and a mild aperient and tonic treatment is usually effectual in removing or ameliorating the complaint. 8. FENWICK.

GASTRIC FEVER (*gastrh*, the stomach). A popular name for a febrile condition attended with prominent gastric symptoms, as well as for typhoid fever. See TYPHOID FEVER.

GASTRIC GLANDS, Diseases of (*gastrh*, the stomach). See STOMACH, Diseases of.

GASTRIC ULCER (*gastrh*, the stomach) See STOMACH, Diseases of.

GASTRITIS (*gastrh*, the stomach).—Inflammation of the stomach. See STOMACH, Diseases of.

GASTRODYNIA (*gastrh*, the stomach, and *dýna*, pain).—A painful affection of the stomach, generally considered as of a neuralgic character. See GASTRALGIA.

GASTRO-ENTERIC (*gastrh*, the stomach, and *étreper*, the intestine).—This term is applied to those morbid states in which the stomach and the intestine are simultaneously affected. The continuity and similarity in structure of these viscera render them peculiarly liable to coincident disease; and this is more particularly noticed in affections of an inflammatory type (gastro-enteritis), or of a degenerative nature. At the same time, as gastritis may occur and run its course without giving any indication that the intestine is involved, so enteritis may be developed with little

or no disorder of the stomach. The same causes appear to determine similar diseases in the stomach and in the intestine; but why at one time both should suffer, and at another time one should escape, is not known. Occasionally it would seem that the entire alimentary canal beyond the œsophagus is attacked at once, and the gastro-intestinal catarrh of children is a good example of this. Sometimes the disorder commences in one part of the canal, and spreads until both the stomach and the intestine are involved. See *INTESTINES*, Diseases of, and *STOMACH*, Diseases of. W. H. ALLCHIN.

GASTROERHCHA (*gastrh*, the stomach, and *éw*, I flow).—An excessive flow of mucus from the lining membrane of the stomach, due to catarrh. See STOMACH, Diseases of.

GELATINIFORM CANCER.—A synonym for colloid cancer. See CANCER.

GENERAL.—This word, as employed in relation to medicine, has several applications. Thus we speak of a *general disease*, which is a disease affecting the whole system, as distinguished from a local affection. As further examples may be mentioned *general debility*, *general paralysis*, and *general droopy*. So, with respect to therapeutics, *general treatment* refers to remedial measures intended to affect the organism as a whole. In connexion with the sciences of therapeutics, pathology, &c., the word *general* is intended to express the essential principles of these sciences, as distinguished from their special divisions.

GENERAL PARALYSIS OF THE INSANE. SYNON.: General Paresis; Fr. *Paralysie générale incomplète*; *Paranirphalite chronique diffuse*; Ger. *Allgemeine progressive Gehirn-ahmung*, *Paralytischer Blödsinn*.

DEFINITION. A gradual loss of the power of coordinated movement, accompanied by gradually increasing mental disturbance and decay.

ÆTIOLOGY.—The subjects of general paralysis are most frequently of the male sex, and between 30 and 50 years of age. It may be brought on by excessive mental labour, by severe anxiety, by alcoholic or venereal excess, or by any prolonged strain upon the mental organisation. It may also be induced by a blow or other direct injury to the head. Hereditary predisposition is probably not without influence upon its production; but this is not so frequently present as in most other forms of insanity. The disease most frequently attacks persons who have previously been apparently in the enjoyment of vigorous health.

ANATOMICAL CHARACTERISMS.—Authorities are not agreed upon the precise nature of the pathological changes characteristic of this disease. The most frequently described lesions are congestion and thickening of the membranes of the brain; and degeneration of the cortical substance, shown by a fatty or shrunken condition of the nerve-cells, and an augmentation of the connective tissue. The degeneration has been traced by some observers into the spinal cord and the sympathetic ganglia.

SYMPTOMS.—1. *Physical*. The physical symptoms of general paralysis of the insane are few apparent in the muscles of articulation and expression. There is an occasional thickening of

stammer, perhaps observable only in the pronunciation of the more complex sounds, and a peculiar convulsive tremor of the upper lip accompanying the least excitement. A similar fibrillar trembling may also be observed in the tongue, when an attempt is made to hold it out. This loss of muscular control gradually spreads over the whole system, its onward course being, however, not infrequently interrupted by very remarkable though generally brief remissions. Before the patient is laid completely prostrate, the affection both of articulation and of gait strongly resembles the failure of coördinate movement produced by drunkenness. In the last stage the patient lies quite helpless; the power of articulation and every kind of voluntary movement are lost, there is also a strong tendency to the formation of bed-sores, and spots of ecchymosis are apt to appear on the application of even gentle pressure. Inequality of the pupils is usual from the commencement of the illness; but they do not often remain long in one condition: sometimes one pupil and sometimes the other being dilated or contracted. A characteristic feature of the disease is the occurrence of convulsive or epileptiform attacks, but they are very variable, both in their frequency and in the stage at which they are first observed.

2. *Mental*. These symptoms generally precede the physical, though some cases occur in which the condition of the mind is not such as to attract attention till some time after the motor symptoms have become obvious. Sleeplessness and general restlessness are usually the first indications of the derangement, and with these may be associated transient states of depression and hypochondriacal fancies. Enfeeblement, shown by forgetfulness and incapacity for continuous thought, is generally an early symptom, and in some cases a gradual increase of this enfeeblement, till absolute fatuity is reached, constitutes the prominent mental symptom. A common condition from the commencement is an inordinate disposition to embark in any, even the most impracticable, undertaking that may be suggested. There is always observed a peculiar facility of disposition, generally good-humoured, but liable to be interrupted by fits of passionate excitement. Frequently there is a very remarkable extravagance, both in thought and act. In most cases acute maniacal attacks take place, in which the excitement presents a specially extravagant character. The semblance of probability and coherence found in ordinary acute mania is generally absent. The prevailing ideas are of grandeur, colossal size, infinite number, power, wealth, and rank, all heaped together in wild confusion. Every such maniacal attack marks an appreciable step in the progress of mental decay; and the tendency is always more or less steadily to complete fatuity. In some comparatively rare cases, especially where there is a tendency to phthisis, the mental condition is mainly one of depression. Remarkable remissions of all the symptoms are sometimes met with.

Diagnosis.—The diseases from which general paralysis of the insane requires to be distinguished are paralysis due to cerebral hemorrhage, embolism, encephalitis, or tumour of the brain; hy-

sterical and tonic paralysis; locomotor ataxy; alcoholic insanity, senile dementia; and muscular atrophy. The diagnosis is generally easy, if attention be paid to the presence or absence of the convulsive tremors in the muscles of articulation at the commencement; the general and progressive course of the loss of coördination, and the peculiar mental facility and extravagance.

Prognosis.—Complete recovery seldom, if ever, takes place in general paralysis of the insane. The ordinary duration of the disease is from a few months to three or four years, though cases of ten years' duration occasionally occur.

Treatment.—In ordinary circumstances the treatment cannot be properly carried out in a private house; removal to an asylum will therefore generally be necessary. Little benefit is to be derived from drugs. The conditions of excitement are held by some to be moderated by small doses of Calabar bean; and turpentine enemata are frequently useful in the epileptiform attacks. The diet ought to be nutritious, but non-stimulating. The food ought to be minced or pulpy, and care should be taken to prevent an accumulation of it in the pharynx, as fatal choking is sometimes produced in that way. If this should be threatened, the tongue should be immediately pulled forward, and the bolus extracted with the finger. On account of the liability to bed-sores, the patient should as long as possible be prevented from lying constantly in bed.

JOHN SIBBALD.

GERMS OF DISEASE.—This is a phrase in common use, the acceptance of which is various, and often more or less vague. So far as it refers to actual things or objects, they also are probably diverse in nature, though at present our knowledge of most of them is based rather upon conjecture than actual experience.

As a phrase, 'germs of disease' is most commonly used in the following modes:—

a. A person may be said to inherit the germs of disease when there is reason to believe that the constitutional, general, or local disease from which he is suffering is of a kind which has been common in the family or stock whence he has descended and when the disease is one which seems prone to manifest itself in this way. It may, in this sense, be said that a person inherits the germs of gout, scrofula, tuberculosis, syphilis, or cancer; and, in either of such cases (with the possible exception of the two latter), no one would, on reflection, be able to find that he meant anything else than that the patient had inherited a certain general disposition, habit, or bodily tendency, in which, under the influence of slight exciting causes, this or that morbid condition should be prone to manifest itself.

b. In a still looser sense, the phrase is sometimes used to signify the mere commencement or initial stage of a certain disease, as when it is said that the germs of a phthisical patient's maledy date from a certain catarrhal attack, or that a patient now suffering from a severe brain-affection contracted the germs of his disease in India or elsewhere, on the occasion of some slight sunstroke. Here the expression would be used in a purely metaphorical sense.

c. The phrase is most commonly employed, however, in reference to the real or supposed causes of communicable morbid processes or diseases, either local or general—those which spread either from part to part in the same person, or from person to person in the same community.

In the spread from part to part, as during the 'generalization' of some malignant new-growth, the agency of 'germs of disease' is, perhaps, not differently more imaginary than real. Results are apt to be ascribed to 'infection' where nothing of the kind has been in operation—as when similar perturbed tissue-changes may chance to manifest themselves, either simultaneously or consecutively, in different parts of the body, as results of some single or similar underlying cause.

In the spread from person to person of local or general contagious affections, the same possible source of fallacy has to be borne in mind. We must be upon our guard against ascribing too general an influence to 'germs of disease.' In certain cases there may have been in the first place non-existent, as when such a disease has been 'antagonized,' and in no sense a derivative of antecedent disease of the same kind. This caution is especially applicable in regard to such an affection as erysipelas—which, although certainly contagious, is also on very good grounds judged to be 'generable,' especially during certain states of lowered health induced by renal disease and some other visceral affections. Though not so certainly known, it is by many deemed probable that a similar caution may be necessary in regard to more general contagious affections, such as diphtheria, typhoid and typhus fever, and cholera, which, though certainly contagious, may also be autogenetic. On this subject, however, much doubt and uncertainty still prevail.

The consideration of this third use of the phrase 'germs of disease,' conducts us naturally to the question as to the nature of the things or objects which may be included under the same name, and this again to the modes in which they operate. As these are questions, however, which have already been discussed under **CONTAGION**, they will only be very briefly referred to here.

The different kinds of contagia, whilst they are all of them to be regarded as products thrown off from the body of a person suffering from a communicable affection, may in essence be either (1) not-living chemical compounds; (2) cast-off and altered tissue-elements; or (3) cast-off micro-organisms of a low type, either in their 'finished' condition or in a germ-stage.

Whilst it cannot positively be said that we have as yet discovered contagia belonging to the first category, our knowledge is a trifle more definite in regard to the existence of those pertaining to the second and third categories. In what proportion these latter kinds of contagia exist, however, for different communicable diseases, still remains to be discovered.

Such different kinds of 'germs of disease' might take effect in two distinct modes, and only in two, since the probable modes of operation of those belonging to the first and second varieties are not at present capable of being discriminated from one another.

First, we have the mode of action of contagia in the spread of local affections, such as ophthalmia, gonorrhoea, and erysipelatous inflammations. Chemical compounds, or diseased tissue-elements, or both in combination, thrown off from such foci of disease, and falling upon suitable situations in other human beings, are capable of determining inflammations of like kind, in which multitudes of new contagia, also of like kinds, are 'independently' produced—that is, are produced otherwise than by processes of organic reproduction. How far such chemical, or 'contact actions' (not necessarily producing inflammations) may take part in, and lie at the root of the very complex group of morbid processes constituting this or that general contagious affection, or so-called 'specific fever,' is not at present known. The processes must be somewhat of this kind, if the operating contagia are not living organisms; and even where they are of this type, it is possible that the same sort of process may obtain.

Secondly, where micro-organisms (bacilli, micrococci, &c.) are the contagia, they are believed to produce their effects by the continuous multiplication, or 'organic reproduction,' of such independent units in the tissues and blood (one or both) of the individual affected. The multiplication of such units, and the chemical changes in the tissues attendant thereupon, are therefore believed to be the sole and efficient causes of the groups of symptoms and tissue-changes constituting the particular general or local communicable disease, and the myriads of contagious elements produced during its progress are regarded as lineal descendants of those which initiated the morbid symptoms.

In the event of its being true, as some hold, that such living organisms are met with in the blood, and are believed to be at times the causes of certain of the communicable diseases, can arise 'independently' within the body (by 'heterogenesis' or by 'archeiosis'), the second assumed mode of operation of contagia would have to be more or less completely renounced in favour of the first. The contagia, even in this latter case, might simply set up morbid processes, which, instead of being simple (as in those caused by the pus-corpuscles and its fluids from some seat of virulent inflammation) might be complex, prolonged, and linked together, so as to constitute the morbid processes typical of some particular specific fever. At some stage of this complicated chain of processes, and somewhere (that is, either in some organ or tissue, or in the blood), organisms may arise *de novo*, which, either alone or with their parent fluids or tissue-elements, are again capable of acting as contagia. But the organisms in such a case could not be regarded as direct descendants of the original contagia, and similarly no one would think of regarding the pus-corpuscles met with in a case of purulent ophthalmia or gonorrhoea, as direct lineal descendants of those which may have taken part in occasioning one or other of such diseases.

H. CHAMBERLAIN BASTIAN.

GIDDINESS (Sax. *gidig*, turning or whirling round).—A synonym for vertigo. See **VERTIGO**.

SINGIVITIS (*glagitis*, the gums).—Inflammation of the gums. See MOUTH, Diseases of.

GLANDERS.—*Stron.*: Equinia; *Fr. Morve*; *Ger. Rots*. Its associated condition is named *Farcy*; *Fr. Farcie*; *Ger. Wurm*; *Hautwurm*.

DEFINITION.—A contagious febrile disease, communicated to man from the horse, ass, or mule, characterised by specific inflammatory lesions of the nasal and respiratory mucous membranes, and of the lymphatic vessels and glands, with general pyrexia, pains in the joints and muscles, and great prostration, usually accompanied by a peculiar cutaneous eruption.

The local manifestations vary in order of appearance, and in comparative severity in different cases. In those in which the nasal and respiratory mucous membranes are earliest or most severely affected, the disease is customarily called Glanders; while to those in which the lymphatic system first and especially suffers, the designation Farcy is applied. But no sufficient reason exists for considering glanders and farcy as distinct diseases. They are commonly associated, and whichever set of symptoms may appear first, the other, as a rule, sooner or later follows. Further, it has been proved that the same virus may give rise to either set of symptoms, or to both. And it would seem that the order of appearance is determined in great measure by the mode of communication of the virus, as well as to some extent perhaps by the condition and constitution of the recipient.

Glanders in man is a very rare disease; and it is only within the last sixty or seventy years that its occurrence has been clearly recognised, and its history made out. When it does occur, it proves fatal in a very large proportion of cases. Taking the acute and chronic cases together, 208 out of 245 are recorded as having terminated fatally. Nevertheless out of 2,026,206 deaths in England and Wales during the four years 1871-1874 only 19 are registered as due to glanders.

ETIOLOGY.—There is no evidence to suggest that glanders ever originates in man, whatever may be the case with regard to the lower animals. It is always communicated, and almost always by direct inoculation of virus from a diseased animal. In some few instances the disease has been communicated from man to man. It is scarcely ever met with except among those who are more or less constantly employed among horses, and who are therefore liable from time to time to come in contact with diseased animals, or the morbid discharges from them. The mode of communication can in most cases be easily traced. The rarity of the disease in man, considered in conjunction with its comparative frequency and the rapidity with which it spreads among horses, would seem to indicate that the virus is fixed, and not readily diffusible through the air, and that man is not very susceptible of its influence.

In most cases the history renders it clear that the virus, in semi-liquid or semi-solid form, has been received through some cut or abrasion of the skin or mucous membrane. In some few instances it appears probable that the virus in similar form may have been absorbed through the unbroken mucous membrane or skin. But

there is at present no sufficient evidence to show that glanders, any more than syphilis, can be communicated by 'a volatile infecting principle,' although by some it is maintained that such communication may take place. If it were so, the disease would probably spread more frequently and extensively, and become comparatively common.

SYMPTOMS AND COURSE.—However the virus of glanders may have been communicated, a period of incubation, varying from three to eight days, and in some rare instances a prolonged even to three weeks or more, ensues before the symptoms of constitutional infection become manifest. The longer the period of incubation the less acute, as a rule, is the course of the disease. The duration of the disease, as well as the order of development of the local affections, varies greatly in different cases. Hence the classification, on the one hand, into cases of *acute*, *subacute*, and *chronic* glanders; and, on the other, into cases of *acute* and *chronic* glanders, and *acute* and *chronic* farcy. But nothing like clear lines of distinction can be drawn between any of these classes.

The earliest constitutional symptoms are a sense of general discomfort, fatigue, prostration, and chilliness, with headache, and obscure pains in the muscles and joints. As the disease advances these pains become more severe, and stimulate those of rheumatism. Pyrexia, at first but slight, rapidly becomes established. The pulse is quickened and sometimes full, the skin hot and dry, the tongue foul, the urine scanty and high-coloured; and the patient suffers much from restlessness, sleeplessness, and loss of appetite, often with obstinate constipation. Sometimes the feverishness is intermittent, but more frequently continual, or intermittent at very irregular intervals. Still later rigors occur, more severe than such as may have occurred at an earlier period, followed by profuse sun perspirations and clamminess of skin; the pulse becomes very rapid, weak and compressible, diarrhoea, with very fecid stools, succeeds the constipation, the thirst is excessive; respiration becomes more and more difficult and laboured; low delirium, with tremors, is followed by coma; and death ensues from exhaustion. In the acute form, the disease runs its course in an average period of about sixteen days, some cases have terminated fatally within a week; others have been prolonged for four weeks. In the less acute form the duration may be from six weeks to two months. And in the most chronic form, in which all the symptoms are less severe, the duration may extend over several months, and in some cases recovery ultimately takes place.

Local Manifestations.—In association with the constitutional symptoms thus indicated, the following local manifestations present themselves, but, as already stated, somewhat differently in different cases.

The wound or abrasion through which the virus has been introduced, or the spot at which it has been applied (for the wound may have healed), becomes inflamed, tense, painful, and surrounded by spreading erysipelatous redness. The ulcer which appears enlarges, assumes an unhealthy, corroded, chancreloid aspect, and discharges dirty sanious and often offensive matters.

The lymphatic vessels of the part become inflamed, and present a knotted, cord-like, and subsequently irregularly modulated condition—the *farcy-hands* in the human subject. The glands are infiltrated and enlarged, and the whole part is swollen and oedematous. The lymphatic glands and vessels of other parts subsequently become affected, but not perhaps to the same extent as in the horse. Resolution and absorption to a greater or less extent sometimes take place; but much more frequently suppuration of low type, abscess-formation, and the production of foul, ulcerating cavities, with hard irregular edges, and fistulae follow. At a variable period in the course of the disease, from within forty-eight hours to the end of three or four weeks, an eruption, regarded as characteristic, appears on the skin. This first shows itself as scattered collections of red spots, 'which are very small and resemble fleabites, and soon acquire a papular elevation, subsequently rising above the level of the surface, like small shot, assuming a yellow colour. They lie in a kind of hole in the corium, as if the latter had been punched out' (Virchow). They appear to be due to the deposit of some neoplastic material, which subsequently softens and breaks down. By-and-by they become vesicular (some say from the first they are vesicular), and then rapidly sero-purulent, with inflamed livid bases. When close together these pustules become confluent, and give rise to irregular ulcerated surfaces, with soft, brownish, sloughy coating. Large collections of similar deposit in the subcutaneous tissue give rise to hard, painful, boil-like formations, which breaking down lead to extensive sloughing of the skin and deeper structures, with thick, dirty white, or sanguineous offensive discharge.

The mucous membranes—and first, and especially that of the nose—are sooner or later affected by specific inflammation and ulceration. Whether the inflammatory process begins in them or in the skin is not clearly made out. It probably does so in many instances, but in some cases in man, as commonly in the horse, the disease is probably communicated by application of virus to the mucous membrane of the nose or other part of the respiratory passages, which thus becomes primarily affected.

When the nose is affected (as is always the case in the form of the disease especially called glanders), there is first a discharge of comparatively thin, colourless, 'catarrhal' mucus. This soon becomes thicker and coloured, and there is considerable pain, heat, redness, and oedematous swelling about the nose itself and the adjacent parts of the face. Ultimately the discharge becomes thick, sticky, tenacious, and semi-purulent, of a dirty yellow or brownish colour, and often stained with blood. In all cases probably there is ulceration of the mucous membrane, following tubercle-like deposits in it, and the ulceration sometimes extends so deeply as to lead to perforation of the septum, or partial destruction of the turbinated or palate bones. The ulceration often occurs only in the upper part of the nose, and the mucous membrane of the frontal and other sinuses is liable to be similarly affected. When the lymphatic and

cutaneous systems suffer first and especially, the nasal mucous membrane is not affected until towards the termination of the case; and in some instances death has occurred before this affection of the nose has taken place.

Bronchial catarrh with rhonchi heard all over the chest, accompanied by severe cough with profuse expectoration, indicates the implication of other parts of the respiratory mucous membrane. The conjunctiva and the mucous membrane of the mouth, gums, fauces, and especially the tonsils, are often affected to a serious extent; so also is the larynx, hoarseness, pain, and difficulty in speaking resulting therefrom.

ANATOMICAL CHARACTERS.—The pathological lesions found on post-mortem examination are such as might be anticipated from the signs and symptoms manifested during life. To these, however, may be added fluidity of the blood; softness and rottenness of the muscles, with hemorrhagic abscesses in them (considered by Billroth as characteristic); patches of grey hepatization in the lungs, or lobular pneumonia; abscesses in the parotid, submaxillary, and cervical glands, &c.

DIAGNOSIS.—The diagnosis of glanders in man may be difficult in the early stage, particularly if the history be defective, and no external wound appear. But when the disease is fully developed, the signs and symptoms, especially if taken in conjunction with the occupation and history of the sufferer, are sufficiently characteristic. In some rare instances, however, in which the constitutional symptoms have been slight, and the local manifestations have very slowly developed themselves, great difficulty has arisen, and the true nature of the disease has not even been recognised until after death. Rheumatism, typhoid fever, and pyæmia, and, in regard to the more chronic cases, syphilis and tuberculosis, are the diseases with which it is said that glanders may possibly be confounded.

PROGNOSIS.—The prognosis in glanders must be extremely unfavourable. Two or three cases only are on record in which recovery has taken place from the more acute form of the disease. In the more chronic forms, however, the deaths have been only about fifty per cent. The more slowly and less severely the symptoms develop themselves, and the longer the patient survives the better is the chance of ultimate recovery.

TREATMENT.—The constitutional treatment should be supporting, stimulating, and soothing, and varied from time to time according to the indications afforded. Quinine in large doses and perchloride of iron may be useful. But at present, although very many drugs have been tried, none has been found having any marked specific effect on the course of the disease. Locally any suspicious wound should be freely cauterized as soon as attention is directed to it. All abscesses and collections of morbid material should, as far as possible, be freely incised, and their contents thoroughly evacuated. The resulting cavities and fistulae should be frequently and thoroughly washed out with disinfectants, and poultices should be applied. The operator, and those who dress the wounds, should wear indiarubber gloves. Inhalations of iodine or carbolic acid vapour should be frequently perfused;

and this being thoroughly syringed from time to time with disinfectant solutions, as carbolic acid, tannic water, or Condy's solution.

ARTHUR E. DURHAM.

GLANDULAR DISEASES.—A general denomination for diseases of glands of all kinds. See BRONCHIAL GLANDS, LYMPHATIC GLANDS, and MINOR GLANDS, Diseases of; also the several special glands.

GLAUCOMA (γλαυκός, sea-green).—In its modern acceptation, this word is used to include all the conditions, whether acute or chronic, primary or secondary, which are produced by heightened tension or increased fluid-pressure within the eyeball. The word was originally applied only to those cases of heightened tension in which there is a greenish opaque appearance behind the pupil. See EYE AND ITS APPENDAGES, Diseases of.

GLEET.—SYNON.: Fr. *Gonée miliaire*; Ger. *Nachtripper*.

DEFINITION.—A urethral discharge, milky, viscid, scant in quantity, appearing as a drop at the meatus urinarius, or as shreds floating in the urine.

ÆTIOLOGY AND SYMPTOMS.—The causes of gleet are:—(1) Chronic inflammation of patches of the mucous membrane of the urethra, remaining after acute gonorrhoea; (2) Chronic congestion (inflammatory or other) of the prostate; (3) Granular patches and warts, and (4) Follicular sinuses.

1. **Chronic inflammation of the urethra.** In the first form, which is by far the most common, the interior of the urethra, naturally pale-pink where unaffected, is dull red, or purplish red, or pale and streaky. These red patches are less elastic than the unaffected parts, and frequently, in course of time, develop into bands of stricture-tissue leading to more or less contraction. The most common positions in order of frequency are, first, the first inch from the meatus; then at 2 to 3 inches, lastly at $4\frac{1}{2}$ to 6 inches, or in the bulbous portion of the urethra. Several months, probably always over six, are needed to develop the patches of inflammation into fibrous lands.

Clap has preceded the present discharge some months, or even a year or two, apparently subsiding altogether for one or two months, and returning again without obvious cause. Pain is either absent; or slight smarting or tickling is felt at the parts chronically inflamed, during micturition or at other times. The precise situation of the inflamed patches is ascertained by passing a bullet-sound or bougie (No. 14 or 16, English) along the passage, or the urethrometer, if the meatus urinarius be too small to admit such a bougie. As the bullet reaches an inflamed spot, slight resistance is noted; and the patient feels pain when it passes over the inflamed or rigid patch. Both resistance and pain cease when the patch is left behind. Should the chronic inflammation have existed long enough to produce fibrous bands, the onward passage of the bullet-sound is checked, or arrested wholly if the bands be too short to permit the bullet to slip past. A smaller bullet or diminution of the urethrometer's bulb allows

the obstruction to be passed, and denotes the degree to which the normal expansile capacity of the urethra has been contracted.

2. **Chronic congestion of the prostate.**—Prostatic gleet is caused by (a) extension of gonorrhoeal inflammation to the prostatic urethra—*chronic prostatitis*; or (b) irritation and congestion of a sympathetic kind, excited by masturbation, excessive coitus, stone in the bladder, or piles—the '*irritable*,' or '*relaxed*' prostate.

(a) In *chronic prostatitis*, with a history of preceding gonorrhoea, there is a scanty discharge, seen only at the meatus when several hours have elapsed since micturition; or there are shreds in the urine. The pain consists of a sensation of heat extending along the whole urethra, often radiating to the buttocks, but felt most *after* micturition. At other times there is dull pain in the perineum, a sense of weight or fulness of the rectum, rather worse when lying down, and by night than by day. Micturition is performed once or twice, or more times, by night. When micturition is attempted, the urine is often slow to come, and usually a few drops dribble off after the stream ceases. Walking fatigues easily, and brings on the sense of fulness in the rectum. The finger in the rectum generally finds no enlargement, but slight tenderness of the prostate. A bullet-bougie or sound, bent one inch from the point at an angle of 135° , traverses the urethra without causing pain till the bulbomembranous part is reached. The instrument is there grasped for a few seconds, to pass on again to the neck of the bladder, here, again, pain is felt and resistance made, the latter ceases suddenly as the sound enters the bladder, though the pain still remains. As the instrument is withdrawn, it is expelled rapidly until it is beyond the bulb, where it lies quietly enough, and all pain ceases. The urine withdrawn from the bladder through a catheter is normal, and free from mucus.

(b) The '*relaxed*,' or '*irritable*,' prostate is caused most often by masturbation, or by unsatisfied sexual excitement, which lead to frequent determination of blood to the prostate, without also obtaining that speedy evacuation of the blood which follows the sedative influence of the natural gratification. The gland is turgid, very sensitive, and tender, the crypts and follicles secreting an abnormal quantity of mucus. The swelling of the gland may be sufficient to alter the shape of the urethra; hence micturition may be impeded, and occasionally accompanied by smarting pain. A dull heavy sensation, hardly amounting to pain, is referred to the anus or perineum; and the pressure of hard faeces during defecation is often distinctly painful. The passage of a bougie along the urethra causes little pain till the prostate is reached, when the patient may even scream with exaggerated expression of the pain he feels. The instrument is grasped by spasm for a few seconds, when it passes into the bladder, and no more pain is felt. The discharge observed by the patient is transparent, colourless, glutinous, scanty, except when he strains, or is excited by erotic desire, when several drops may come away at a time. In middle aged men urethral stricture is sometimes

also present, and aggravates the prostatic irritation. The reflex and sympathetic derangements attract more attention than the local condition. An almost invariable accompaniment, if not a consequence, is dyspepsia with its various symptoms; very common, also, are aches and pains in the lower extremities, loins, and other parts. There is often great weariness, especially after sexual intercourse. Intellectually and morally the patient is much affected. Dread of impotence, of loss of memory, of insanity, or even of paralysis, is often a leading symptom.

3. **Warts and granular patches**.—Warts, which are most commonly situated just within the meatus, may stud the whole length of the urethra. Near the meatus they are arborescent, lower down sessile or only slightly pedunculated. Identical in structure with the warts on the glans or furrow of the penis, they are ordinarily papillomata.

4. **Follicular sinuses**.—Follicular sinuses, inflamed during acute gonorrhoea, often secrete discharges long after the gonorrhoea is ended. In the anterior urethra rarely more than one or two crypts are thus chronically inflamed, but in the prostatic portion several crypts secrete a thin translucent fluid, and this form may be looked on as one of chronic prostatitis. In cases of hypospadias, at the extreme end of the exposed urethra, there is in many persons on each side of the orifice a natural crypt three-quarters of an inch long. These often continue to discharge thin mucus-pus long after gonorrhoea has subsided. Other sinuses, but shorter ones, open in the situation of the lacuna magna of the normal urethra. None of these follicular sinuses ever form indurated patches in the substance of the urethra, hence they never cause stricture. This may, however, sometimes result from the bursting of an inflamed and suppurating sub-mucous gland, which before its evacuation may have projected on the wall of the urethra, and thus temporarily produced a narrowing. The discharge from such a cavity is much more copious than from a simple follicle, and very slow to dry up, though that usually happens spontaneously if there be no stricture to prevent the easy outflow of the urine.

TREATMENT.—1. *Inflammatory patches*.—When the pain experienced from passage of the exploring sound is acute, the resistance small, and the discharge white and thick, the condition is mainly one of congestion, and the injection of three or four minims of a solution of ten to twenty grains of nitrate of silver to the ounce, by means of a Guyon's bullet-catheter and syringe at the places where pain is felt is then a useful measure. This may be repeated in three or four days, if needed. If there be cling or hitch as the bullet passes along the urethra, the passage of a full-sized (No. 25 or 26, French) metal sound twice weekly is requisite. When no cling exists, the last remains of the discharge may be dried up by using soluble bougies at night ('*Porte remède Reynal*') for ten to fourteen nights. When congestion has become induration, or even contraction, which does not yield to gradual dilatation, the fibrous band should be divided by a urethrotome of suitable shape, until the urethrameter, expanded to the largest size in which it moves

freely along the unaffected parts, travels without hitch or cling past the contracted patches.

2. *Chronic prostatitis*.—Usually the cure is slow, and depends much on regimen and diet; with abstinence from alcohol, fatigues, lascivious thoughts, and sexual excitement. To relieve pain and irritation, mild belladonna and opium suppositories may be employed; when the discharge is opaque and tolerably copious, two minims of copaiba in essence of cinnamon and water, or a drachm of solution of sandal-wood oil, with buchu and cubeba, are useful. Locally, when the prostatic tenderness has subsided, cool hip-baths for five minutes night and morning, beginning at 85° F., and gradually lowering the temperature to 60° F., are beneficial. After a week or two the bath may be taken at 50° F., and lowered by ice to 40° F., with advantage. The sitting should not exceed five minutes, but the baths should be continued for several weeks. Counter-irritation is most useful when there is pain and considerable irritation. It should be applied over a large surface by the caustic solution of iodine. It is at best an uncertain remedy.

The 'relaxed' prostate requires great tact and perseverance for its cure. Regulation of the digestion, prescription of suitable occupation, and encouragement of the patient to throw off his mental dependency comprise the general treatment. Locally, if the prostate be not extremely sensitive, the passage of the steel sound on alternate days is most beneficial. Dreaded as is the first passage of the sound, the relief that follows is so satisfactory that the patient seldom objects, and generally demands its repetition. When the passage of the instrument is really agonising, the patient should be anaesthetised, his bladder emptied by catheter, and ten to twenty minims of a twenty-grain to the ounce solution of nitrate of silver thrown into the prostatic-membranous urethra by Thompson's prostatic injector. This may be followed by a subcutaneous injection of one-third of a grain of morphia before the patient recovers his consciousness. He should keep his bed for one or two days afterwards, and his pain three or four days more. Repetition is seldom required, as the sound is then well borne. As a completion of the cure, a long voyage and a year spent in Australian or New Zealand sheep-farming are most useful.

3. *Granular patches*.—These are best treated by passing along the urethra a bougie, which has been dipped for three inches or more into an ounce of melted cacao butter holding suspended in it five to ten grains of peroxide of mercury or nitrate of silver. When cold, this bougie may be inserted into the urethra for ten or fifteen minutes, till the warmth of the body has melted off the cacao butter, by which plan the stimulant is directly applied to the granular patch. Again, twenty drops of a thirty-grain to the ounce solution of nitrate of silver may be thrown on to the granulations by a bulbous syringe. These strong injections should be made only when the patient can rest in his room for twenty-four hours afterwards. The pain is sometimes severe, and needs hot baths, opium, and other anodynes, to allay it.

Warts should be exposed by an aural specu-

him at endoscopy, and touched by a wire armed with tannic caustic.

4. *Follicles*.—The follicles can also be reached through the speculum, and a slender wire armed with caustic run into the mouth of the follicle. Usually, when the discharge is due solely to follicles, it is better left alone. The long sinusses met with at the end of the urethra in hypospadias may be first cauterised; and then, if caustic be not sufficient, slit up with a fine knife and canaliculus-director. **BRECKLEY HILL.**

GLEICHENBERG, in Austria. Muricatal alkaline waters. See MINERAL WATERS.

GLOBUS HYSTERICUS (*globus*, a ball, *hysterica*, connected with hysteria)—**SYNON**: Fr. *globe hystérique*; Ger. *hysterische Kugel*.—A subjective sensation experienced by hysterical patients, as of clicking, or of a ball rising in the throat. See HYSTERIA.

GLOSSALGIA (γλῶσσα, the tongue, and ἄλγος, pain).—Pain in the tongue. See TONGUE, Diseases of.

GLOSSITIS (γλῶσσα, the tongue).—Inflammation of the tongue. See TONGUE, Diseases of.

GLOSSO-PHARYNGEAL NERVE, Diseases of.—The glosso-pharyngeal nerve is the special nerve of taste for the lack of the tongue and the soft palate, and of common sensation for the same region, and in part for the upper portion of the pharynx, the eustachian tube, and the tympanum. It is also the motor nerve for the stylo-pharyngeus, the middle constrictor of the pharynx, the levator palati, and the axygus uvulae muscles. It is doubtful whether the fibres for the two latter muscles arise from the roots of the glosso-pharyngeal.

Paralysis.—Very little is known of the precise effects of paralysis limited to the glosso-pharyngeal nerve, since it is very rarely paralysed alone. Sensation in the fauces is certainly lost, and also taste in the back of the tongue and palate, perhaps also to a slight extent in the front of the tongue. The middle constrictor of the pharynx is paralysed, and perhaps also certain movements of the palate and the uvula. From their position, the fibres of origin are commonly damaged in conjunction with fibres of the hypoglossal, spinal accessory, and pneumogastric. The common causes of damage in this situation are meningitis, syphilitic and other growths, and bone-diseases. The nerve may also be paralysed from disease of its nucleus of origin in the medulla oblongata, and then commonly in association with the nerves to the larynx, the tongue, and often the lips (see LARINO-GLOSSO-LARYNGEAL PARALYSIS). The sensory part of the nerve may then escape, and only the motor part be paralysed. The causes of paralysis from disease of the nucleus are slow degeneration, softening, hæmorrhage, and probably the effects of diphtheria. In diagnosing paralysis of the levator palati and axygus uvulae, care must be taken to remember how often the arches of the palate are unequal, and the uvula is oblique, under normal conditions. Defects of movement must be looked for, and especially the unequal dimpling of the base of the uvula in the pronunciation of 'ah'!

Spasm.—Nothing is known of separate spasm

in the muscles supplied by the glosso-pharyngeal nerve. In conjunction with the other motor and sensory nerves to the pharynx, it takes part in the production of the spasm of hydrophobia, and in some hysterical phenomena. For over-action in the special sensory function of the nerve, see TASTE, Disorders of.

TREATMENT.—The treatment of disorders of the glosso-pharyngeal nerve is never special, but always that of the cause, and is sufficiently described in the several articles which deal with the above-mentioned ætiological conditions.

W. R. GOWERS.

GLOSSO-PHARYNGEAL PARALYSIS.—A synonym for Larino-glosso-laryngeal paralysis. See LARINO-GLOSSO-LARYNGEAL PARALYSIS.

GLOSSY SKIN is the name given to a peculiar atrophic condition of the skin, seen principally in the hands, in consequence of irritative lesions of the nerves of the forearm. The skin of the back of the hand, fingers, and even that of the palm is thin, smooth, shining, without furrows, and redder than natural—either uniformly or in patches. The skin seems as if it were stretched over subjacent parts, which are firmer than natural. It may be more or less fissured, or even denuded of epidermis in patches. Secretion of sweat may be increased or altered in quality. The parts may or may not be the seat of neuralgic pains. It was thought by Paget (who described this condition in the *Medical Times and Gazette* for May, 1864) to be a very rare affection, but it was observed by Weir-Mitchell and his colleagues, in the late American war, no less than 19 times in 50 cases of partial division of the nerves of the forearm. It may occur also as a sequæ of dislocations of the wrist, where the median nerve is compressed or otherwise damaged.

GLOTTIS, Diseases of.—See LARYNX, Diseases of.

GLYCOSURIA (γλυκός, sweet, and οὐρον, urine).—A condition of urine in which sugar is present, generally used as a synonym for diabetes. See DIABETES.

GOÏTRE.—**SYNON**: Bronchocele; Derbyshire Neck, Fr. *Goître*; Ger. *Kropf*, *Struma*.

DEFINITION.—Simple hypertrophy, or cystic, fibroid, or fibro-cystic enlargement of the thyroid gland.

ÆTIOLOGY.—*a. Locality*. Goitre is prevalent in magnesian-limestone districts, for example, Derbyshire—hence the name 'Derbyshire neck.' Amongst the continental countries it prevails in are France, mostly in Savoy, Germany, mostly in the Black Forest; Austria, mostly in Styria; Northern Italy, mostly about the Alps; Switzerland, mostly in the Valais; and Russia, mostly about the Altai mountains in Siberia.

b. Water-supply.—Whenever goitre has arisen without being inherited the cause in far the greater number of cases can be traced to some impurity in the potable water. What this impurity is, has not as yet been satisfactorily determined, although it has been proved that the water used in goitrous districts has percolated through a soil which contains an impurity, which is the cause of the malady. Snow-water was in

former days considered to be the cause, but this opinion is met by the statement that goitre does not exist in Greenland or Lapland, and that it is prevalent in Sumatra, where there is never any snow. The impurity is stated by many to be due to an excess of lime and magnesia, which theory seems borne out by a geological examination of the localities in which goitre is indigenous in England. In the Indian Punjab, where goitre affects 60 per cent. of the population, 59 grains of lime have been found in a gallon of water, 10 grains being an undesirable proportion (Professor Frankland). The latest authorities on the cause of goitre believe the impurity to be of a metallic nature (probably some form of iron), and have shown that metalliferous earths, it may be said almost without exception, are to be found in the neighbourhood of the magnesian limestone districts, where goitre prevails. In many limestone localities also bronchocoele is entirely absent. Scotland, Ireland, Norway, and Sweden are comparatively exempt from the disease, although mountain limestone is found largely present in their geological formation. Why potable water is the cause of goitre has yet to be definitely determined.

c. Other causes.—Epidemics of goitre have been notified, as chiefly occurring amongst soldiers in France, probably the result of forced marches through goitrous districts, combined with scarcity of food. In such districts the practice of carrying loads on the head seems largely to increase the ratio of the disease. The notion that goitre is indigenous to mountainous districts only is set aside by the fact that in some plains, those of Lombardy for instance, goitre is present. Many other theories have been suggested.

Women in this country are much more liable to suffer from bronchocoele than men, perhaps on account of their being more frequently water-drinkers, for in India it has been noticed that both sexes suffer alike. During the time of puberty the disease commonly first appears, although it may occur from any time of life up to forty years of age, children having even been born with a thyroid enlargement.

ANATOMICAL CHARACTERS.—The whole of the thyroid gland, or both lobes or one lobe only, may be the seat of the goitrous enlargement. The isthmus is rarely affected by itself. In exceptional cases an accessory lobe is present, and becomes enlarged. The enlargement may be simple soft hypertrophy of the gland, cystic, or fibroid; or cysts may be found interspersed in the substance of a fibroid enlargement. Cysts are formed from the normal follicles of the thyroid, by their distension with colloid material, the epithelial lining degenerating as the cysts increase in size. The cyst-wall is formed by the inter-lobular septa and capsule of the gland. In pure cysts the serous fluid which is secreted from the walls replaces the colloid contents. In the fibroid form the connective stroma increases at the expense of the follicles, and tough bands of nucleated fibrous tissue traverse the organ in all directions, the change generally commencing centrally and extending peripherally. The follicles mostly atrophy, but some may persist in the form of small cysts.

Goitres in some countries are allowed to reach

such dimensions that the inhabitants have to support them in bags. A cystic goitre, as a rule, projects externally, but often the fibroid variety does not.

SYMPTOMS AND COMPLICATIONS.—The appearance of the swelling, and a sense of fulness in the neck, are often the only symptoms of goitre. Added to the sense of fulness, there may be a feeling of dragging or constriction about the throat. More serious symptoms are sometimes present, namely, dysphagia and dyspnoea. The former is rarely present except when the tumour has reached an immense size, or when it presses on the œsophagus, as happens when the lateral lobes meet behind the gullet. Dyspnoea, a more common symptom, may be due to pressure from the goitre on the front and sides of the trachea (found more commonly in young people, before the tracheal rings have gained much power of resistance), or on both recurrent laryngeal nerves, causing partial paralysis of the abductors of the vocal cords (cricæ-arytenoidæ-postici muscles); or to a portion of the gland passing behind the trachea, or becoming enlarged beneath the sternum. There is often a temporary enlargement of a goitre during the menstrual period and pregnancy, and flooding in childbirth is not uncommon. A tendency to the hæmorrhagic diathesis has been noted. Exophthalmos, with palpitation of the heart, may accompany goitre. See EXOPHTHALMIC GOITRE.

Cretinism is met with, but rarely, in the goitrous districts of this country. More than half the number of cretins are born of goitrous parents, but a goitrous enlargement need not necessarily be present in a cretin, for instances of cretinism have been reported in which the gland has been entirely absent, still they have the same ætiological connection. When the thyroid gland is absent and cretinism prevails, Dr. Hilton Fagge believes that fatty tumours will be found, almost without exception, in the posterior triangles of the neck.

DRAINAGE.—A soft hypertrophy of the thyroid gland can be diagnosed by its general diffusiveness, and the want of consistent hardness.

The presence of a cystic goitre can be ascertained by the fluctuation of fluid within its walls. Illumination of the neck for the purpose of diagnosis is of no use. Any doubt can be cleared up by passing a very fine trocar into its centre. Owing to the fact that some cystic goitres contain a large amount of soft trabecular structure, the fluid withdrawn is likely to be mixed with blood. When the fluid has been entirely withdrawn from a pure cyst, it often happens that blood will be freely discharged from the mucous walls.

A fibroid enlargement of the thyroid gland can be diagnosed by the consistency and hardness of its substance. In some cases, fibroid nodules lie scattered in a general hypertrophy of the gland, and may be of stony hardness. Some difficulty may be experienced in distinguishing between a globular fibroid and a small cystic goitre that has thick walls, both of which lie deeply in the neck; but if the exploratory examination be made, as recommended above, the difference can at once be recognized.

The diseases which simulate goitre are cancer

of the thyroid gland; calculus imbedded in its substance; lymphadenoma; aneurism; and fatty and other tumours of the neck. A leading point in making a diagnosis is to ascertain, by directing the patient to swallow, whether the swelling is attached to the trachea. In the cases of cancer and lymphadenoma, the history and general condition of the patient will give a leading clue. In connection with cancer, it must be borne in mind that a fibroid enlargement of the gland may become the seat of carcinomatous change. When a fibrous goitre closely overlies the carotid artery, a forcible palpation is conveyed through the tumour, simulating an aneurism.

Prognosis.—The prognosis in goitre is very favourable. The occurrence of death from suffocation, due solely to the effects of a goitrous enlargement, is extremely rare. It occurs in those countries where little or no treatment is tried, the tumours being allowed to attain an immense size—their weight sometimes reaching several pounds. The disease is more likely to endanger life when the gland passes behind the trachea and completely embraces it. All the varieties of goitre are amenable to treatment, but especially the cystic. Goitres have been known to disappear without any treatment. This result may be due to the removal of the affected person from endemic influences; or it may happen when the enlargement has arisen during pregnancy.

Treatment.—The general rules requiring attention are removal of the patient from a goitrous district, or complete abstinence from drinking water, unless it has been ascertained to be perfectly pure. General medicinal remedies are of only of service when the gland is enlarged by fibroid change, and then iodide of potassium (two to three grains twice a day), with or without iron, may be tried. When the hypertrophy is of the simple soft form, blistering, or painting the surface with the tincture of iodine, or the use of iodine ointment, will be sufficient. If the enlargement is fibroid and of some consistence, then injections of the tincture of iodine into, or setons passed through, the substance of the gland, are most useful. Fluoric acid has been given internally, with or without the injections (*Lancet*, March 19, 1881). The injection of mxv to ij of tincture of iodine should be used twice a week, then weekly, and afterwards fortnightly. The greater number of cases answer well to this treatment, whilst on others no impression can be made. The time the treatment takes depends on the size of the goitre; a month is the minimum required for the cure of a very small goitre. The process to be followed when injecting is as follows:—Having frozen the skin over the portion decided upon for injection, by means of the ether spray, and care being taken to avoid transfixing any vein or the trachea, the needle of the syringe is pushed into the substance of the goitre, and the fluid injected slowly. The best form of syringe for the purpose is one similar to that used for hypodermic injection, made with a screw-piston. Pain in the course of neighbouring nerves is sometimes felt during the injection, for instance in the ear or at the root of a tooth. When the operation is finished, the needle should be rapidly withdrawn, and the skin where the puncture has been made rolled between the

finger and thumb, to prevent any escape of the iodine. If the needle be passed well into the substance of the goitre, no fear need be entertained of the formation of an abscess. In favourable cases there will be a gradual enlargement of the tumour, with a slight degree of pain, for some eight or twelve hours, after that time the bronchocle will very slowly decrease in size. As a rule, in two or three weeks time it will be evident whether the injection is to prove effective. By this form of treatment all scars are avoided. The length of time required for its adoption is often an objection, even when improvement is noted; a case occurred in the writer's experience in which the time needed for the completion of the cure was over a year, the neck being reduced from $17\frac{1}{2}$ to $13\frac{1}{2}$ inches. Setons made of from two to eight lengths of silk form a very serviceable plan for the treatment of fibrous goitres. In employing either injections or setons it is not necessary for the patient to discontinue his usual employment.

Bimiodide of mercury smeared over the enlargement, the patient being then made to sit with his neck exposed to the rays of the sun for many hours, has proved an effectual remedy in India. A Captain Cunningham, the originator of this plan, treated gratuitously about 60,000 natives in two years. He is said to have never produced salivation, and to have rarely failed in effecting a cure. Ligation of the thyroid arteries has only proved of temporary benefit. Division of the isthmus has been advised when dyspnoea is present. A goitre may be removed when it endangers life or keeps the patient from work. The operation is one of comparative safety under the antiseptic system, and when each vessel is divided between ligatures.

The treatment of cystic goitre is of one kind, and is always successful. The plan consists in emptying the cyst with a trocar and canula, and then injecting a solution of iron (two drachms of the tincture to an ounce of water) sufficient to expand the cavity again. The patient should be kept in bed on account of the rise of temperature, after a successful injection with the canula plugged, until the third or fourth day, when a suppurative discharge should have been set up. The metal canula should then be replaced by an india-rubber one (made with a middle layer of webbing), the canula being cut shorter as the cyst becomes smaller, and poultices applied until the goitre has disappeared. A cure will be effected in one month to four or five months.

During the injection of the iron-solution into cystic goitres, it may happen that air passes into a vein which has been wounded by the trocar. As this accident has been followed by instantaneous death, the writer, to prevent this accident, uses conjointly the two following plans, taking care to avoid superficial veins.—1. A tape is passed round the neck under the base of the goitre, and held tightly by an assistant standing behind the patient, whilst the injection is going on, and for two or three minutes after. 2. The nozzle is fixed at right angles to the body of the syringe, enabling the injection to be made without holding the syringe below the level of the opening into the cyst, and preventing the injection of air. See THYROID GLAND, Diseases of.

PUGH THORNTON.

GONAGRA. (*γόνις*, the knee, and *ἀγρᾶ*, a seizure).—An attack of gout in the knee. See GOUT.

GONARTHRITIS (*γόνις*, the knee, and *ἀρθρῶν*, a joint).—Inflammation of the knee-joint. See JOINTS, Diseases of.

GONORRHOEA (*γόνις*, seed, and *ῥοή*, I draw).—*SYNON.* Clap, Blenorrhagia; Fr *Chauldriac*, Ger *Tripper*.

DEFINITION.—A contagious purulent inflammation, affecting, in men, the urethral mucous membrane and its continuations, in women, the vaginal mucous membrane and its continuations. Occasionally the conjunctival and rectal mucous membranes, to which the nasal has been added on doubtful evidence, are attacked by gonorrhoea. Certain rheumatoid affections and other complications, to be hereafter mentioned, also attend the disease.

ÆTIOLOGY.—The causes of gonorrhoea are *predisposing* and *exciting*. The chief *predisposing* causes are the lymphatic temperament; great sexual excitement and other fatigue, alcoholic excess, gout, previous attacks, especially an uncurd gleet, and lastly, a peculiar proneness to urethritis in certain persons. The *exciting* causes include:—(1) Contagion with (a) gonorrhoea pus, or (b) acrid discharge not generated by gonorrhoea; (2) excessive irritation of the urethra by prolonged or repeated coitus, (3) masturbation, (4) instrumentation; and (5) the use of injections after coitus.

Gonorrhoea differs so considerably in the two sexes, owing to the diversity of seat of the disorder, that its description may be conveniently divided into two parts.

(A.) Gonorrhoea in the Male.—

ANATOMICAL CHARACTERES.—The seat of urethritis is at first the mucous membrane of the fossa navicularis, whence it travels onwards, commonly not extending further than to the bulbous or membranous portion of the urethra. The inflammation then dies away gradually, leaving patches of the mucous surface here and there still inflamed. But the inflammation may extend to the submucous tissue, to the glands about the urethra, to the prostate, to the neck of the bladder, and to the epididymis in one direction, or to the bladder or even to the kidneys in another. Renal inflammation nevertheless is most frequently excited by sympathetic irritation, when the neck of the bladder is attacked, and only with excessive rarity by continuous extension along the bladder and ureters. As the inflammation localises itself in the urethra, it penetrates more deeply, reaching the follicles and submucous tissue, and may thus cause thickening and induration of the urethra at these points.

In the acute stage there is general uniform congestion; as inflammation subsides, the general redness becomes patchy, arborescent, and punctiform. The swelling disappears, leaving areas of thickened mucous membrane, fine granulations which develop occasionally into warts, and a plugged condition of the ducts of the submucous and mucous glands, which possibly may cause peri-urethral abscess or subsequent gleet. After a lapse of time the indurated patches may contract, and thereby cause irregularity and stricture of the urethra.

SYMPTOMS.—The length of the interval between contagion and the development of the symptoms in gonorrhoea varies from twelve hours to eight days; but the great majority of cases are evident on the fourth or fifth day after intercourse. Usually early manifestation of inflammation denotes a severe attack. Urethritis from contagion differs in no respect from inflammation otherwise excited, and has no necessary period of incubation.

In the first stage, redness, scanty sticky discharge, and smarting in micturition are the leading symptoms. Febrile disturbance at this early period is most rare. On the other hand, the discharge in many cases precedes all other symptoms. Towards the end of the first week, swelling generally of the penis, especially of the urethra, sets in, accompanied by copious yellowish-green discharge, smarting in the urethra, and aching in the penis, perineum, and groins. Painful micturition and erections at night are frequent (see CHORDA); and general febrile disturbance is sometimes present. Naturally the disorder subsides in four or six weeks, by gradual cessation of the symptoms, but it is frequently prolonged or brought back to its first intensity by neglect of the precautions necessary against irritation.

The patients' habits often induce variations from the ordinary course, as regards the amount of discharge and the severity of the symptoms. In all cases relapses or re-kindling of the acutely inflammatory stage are common. The acute stage of the disorder terminates in one of three ways:—Cessation of pain and discharge; cessation of pain, with diminution of the still purulent discharge; cessation of all symptoms, except a minute quantity of thin whitish discharge or gleet. This scanty discharge is most commonly caused by chronic inflammation at one or two places, continued after the inflammation has ceased elsewhere. Sometimes a stricture, a small wart, or a relaxed prostate secretes shreds of mucus, and thus causes gleet. See GLEET.

Thus the course of gonorrhoea has been divided into four stages:—*Preliminary congestion*, lasting three or four days; *acute increasing inflammation*, lasting ten to twenty days; *stationary stage*, of uncertain duration; and, lastly, *subsiding stage*, also of uncertain duration. The discharge varies from its usual form of yellow pus, being in some cases viscid, like mucus, in others brown and very liquid; in rare instances it is foamy or pinkish for some days.

DIAGNOSIS.—The distinction of urethritis caused by contagion from that excited by other causes is impossible when the history of the patient's antecedents is wanting. Certain complications of gonorrhoea are said to follow urethritis only when that is excited by contagion. This proposition is not so clearly established that it may serve to decide the origin of a given case to be contagious or non-contagious. To distinguish urethritis from urethral chancre is easy: urethral chancre is never more than one inch from the meatus, nearly always situate just within the entry, and the ulcerated surface can be seen if the lips of the urethra be separated, or a short aural speculum be introduced. The discharge also from a chancre is not creamy, but

cloudy. The pain in micturition is stinging, but limited to one spot. Syphilis may accompany urethritis, but the disease has its proper initial sore or other characteristic symptoms. Occasionally a slight mucopurulent discharge without pain or much swelling is present during the period of the initial lesion in syphilis. This always subsides spontaneously in one or two weeks. In balanoposthitis (*gonorrhoea aeterna*) there is no urethral discharge. When the free border of the prepuce is exceedingly small, it may be most difficult to be certain that the discharge does not come from the meatus urinarius as well as from the surfaces of the prepuce and glans. Usually, a thorough syringing under the foreskin will wash away the pus, and permit the meatus urinarius to be watched while the urethra is pressed, if pus oozes forth it is secreted in the urethra. Abscess of the prepuce or perineum may cause urethral discharge, which is distinguished from gonorrhoea by the history and condition of the patient.

Prognosis.—The prognosis of gonorrhoea is favourable if proper precautions be taken early. But in spite of precaution, the disease is sometimes most severe, especially in young men of lymphatic temperament, or in men of nervous irritable constitution. Gonorrhoea is said also to be liable to run a severe course in persons who suffer from syphilis. During its continuance any of the complications hereafter mentioned may arise. Further, gonorrhoea has caused death through pyæmia; and more often still it originates ankylosis or destruction of joints, or other painful disfigurements, while it is the predominating cause of stricture.

Treatment.—The treatment of urethritis may be (1) *abortive*; and (2) *systematic*. *Abortive* treatment is intended to cut short the disease by large doses of specifics, or by caustic injections, before acute inflammation arrives. It is always dangerous, and rarely successful. *Systematic* treatment consists in at first removing all sources of irritation and allaying acute inflammation. Abstinence from alcoholic liquors, sexual excitement, and severe exercise is necessary. Tepid baths and great cleanliness, with support for the penis and testes, are useful. Painful micturition is often relieved by immersing the penis in ice-cold water during the act. A light diet of fish, milk, and vegetables, with salines and laxatives, should be ordered. When the acute stage is passed, the continuance of the congestion is shortened by astringent injections and the administration of copious, sandal oil, and cubeba. But these should be withheld while there is smarting, copious greenish discharge, and dull red congestion of the urethra.

Complications and Sequelæ.—The complications of gonorrhoeal urethritis are—(1) Balanoposthitis; (2) Phimosis or paraphimosis; (3) Retention of urine; (4) Lymphangitis and Adenitis (Sympathetic bubo); (5) Hemorrhage from the urethra; (6) Peri-urethral abscess (a) near the glans; (b) between the layers of the perineal fasciæ; (c) Cryptitis; (7) Inflammation of the neck of the bladder; (8) Prostatitis; (9) Inflammation of the spermatic cord, epididymitis, and orchitis; (10) Inflammation of the rectal mucous membrane; (11) Conjunctivitis by contact; (12)

Scleritis and tritis; (13) Rheumatism of the sacro, great nerves, or joints; acute synovitis, bursitis, abscess, pyæmia; (14) Stricture; and (15) Warts. Several of these complications are described in special articles, to which the reader is referred; but a few of them require brief notice here.

Stricture, or the development of tough fibrous bands in the submucous tissue in limited areas of the urethra, which prevent the canal from expanding during the flow of urine, is caused by long-lasting congestion and inflammation; the most common seat being the penile portion of the canal, and especially the inch nearest the meatus urinarius, whilst those causing most trouble are commonly at the bulbo-membranous portion. Slowly produced, these contractions seldom attract attention till two or three years have elapsed, and very frequently not until eight or ten years have passed away.

Easily curable, in the early stages, these contractions, by exciting reflex irritation, first of the bladder, subsequently of the kidney, indirectly cause parenchymatous induration and atrophy of the secreting tissue of the latter, and thus seriously affect the nutrition of the body, thereby generating a long chain of morbid changes, which not infrequently end in death.

Retention of urine is produced by gonorrhoea in two ways:—(1) During the acute inflammatory stages by muscular spasm closing the congested mucous membrane at the bulbo-membranous portion. This is of course a temporary evil, though often very painful while it lasts. The bladder should at once be emptied by passing a small (No. 6 or 7 English scale) flexible catheter, and the recurrence of the spasm prevented by saline purges, rest, warm baths, and opiates. (2) In the tightly-narrowed urethra, when stricture has formed, a small amount of local swelling or spasm may block the passage. The immediate treatment consists in passing a catheter fine enough to get through the contraction with the adjuncts just mentioned, and subsequently dilating the contracted parts by one of the various methods employed by surgeons for that purpose.

Hæmorrhage from the urethra is caused by rupture of the blood-vessels of the corpus spongiosum during the violent erections of ebullies. Rarely copious or serious, in some cases it has, like hæmorrhage from other trivial causes, been dangerous from its obstinacy. Ice-cold wrappings, notably the india-rubber coil with ice-cold water flowing through it, generally arrest the bleeding speedily. If requisite, a catheter may be passed and the penis compressed by a bandage tightly wound round the organ.

Inflammation of the neck of the bladder, or, as it is often called, inflammation of the bladder, though real cystitis is rare in gonorrhoea, consists of extension of the mucous inflammation to the neck of the bladder, and is a tedious, often very harassing accompaniment of gonorrhoea. It seldom occurs until the gonorrhoea has lasted two or three weeks, and it may develop at any time during the continuance of that disease. It is denoted by very frequent calls to micturate; great pain during, and especially scalding at the end of micturition, caused by muscular spasm of the deeper peri-urethral muscles, with extrusion

along with the last drops of urine of a small quantity of mucus or blood. The usual gonorrhoeal discharge ceases almost entirely during the attack, but usually returns when the inflammation of the neck subsides. Never dangerous, this affection derives its importance wholly from the great amount of distress, mental and bodily, which it causes. It is best combated by rest, warm baths, anodynes, and very light diet. It is very prone to relapse.

Prostatitis, that is, inflammation of the substance of the prostate, is a severe complication. It causes swelling of the prostate; painful, slow micturition, and often complete retention, a sense of fulness or weight at the anus; and sometimes great irritation of the bowel, with constant desire to defecate. Prostatitis may cause abscess, and usually leaves enlargement of the organ. If suppuration takes place, pain increases till matter escapes, then sudden relief follows. The abscess most commonly opens into the urethra, and the pus comes away with the urine, but it may open into the rectum, the perineum, or the bladder.

The treatment consists mainly in allaying irritation and pain by hot baths, fomentations, and opium; and when retention occurs, the regular passage of a catheter is requisite. When fluctuation is evident, abscesses must be opened in the rectum or perineum. When the abscess has burst spontaneously, it usually closes in course of time, and the discharge ceases altogether or dwindles to a scanty gleet of no importance. Should the discharge continue copious without abatement after several weeks, or the patient suffer much distress, an incision through the perineum is proper, through which to drain and close the abscess.

(B) **Gonorrhoea in the Female—Vaginitis.** This may be acute or chronic. The inflammation begins at the fore part of the vagina extending to the uterus in one direction, and to the urethra in the other. When attacking the vulva, it causes occasionally abscess of accessory parts, for instance, of Bartholin's gland, or of the lymphatic glands. In the cervix uteri and in the urethra it becomes very obstinate.

Symptoms.—These consist, in the acute stage, of swelling of the genitals, heat, or itching, smarting on making water, and itching pains in the back and loins. The mucous membrane becomes dry and bright red. At first the mucus is thin and transparent, but soon becomes thick, creamy, and copious. The mucous membrane is more or less studded with little eminences (*vaginitis granulosa*). The inflammation becomes chronic in from six to ten or twelve days, the pain, swelling, and congestion diminish or cease, the discharge, less creamy, remains plentiful. It is usually secreted in the cul-de-sac, or in the cervix, or some other part less easily cleared than the anterior part of the vagina. These parts, while inflamed, retain a brighter red colour than the rest of the mucous membrane. Not infrequently, when the inflammation has ceased in the vagina, pus can still be squeezed from the meatus urinarius or some of the crypts opening round that orifice, if the finger be drawn forwards along the under surface of the urethra.

The duration is extremely variable; if assiduously treated, so that extension to the cul-de-sac

or cervix uteri is prevented, the disease has a duration of about three weeks. But when these parts or the urethra are invaded, the duration is most uncertain, the disease lasting often for months or even years. The length of time that the discharge remains contagious is also most uncertain. Probably any discharge, however scanty and serous it may have become, may cause disease if increased by accidental irritation.

Diagnosis.—This depends on the swelling and red congestion in the acute stage, and on the purulent excretion and copious discharge in the chronic stage. The distinction between vaginitis from contagion and vaginitis from non-specific irritation is always difficult, and sometimes impossible, being mainly determined by collateral evidence. It generally has a contagious origin if there be pus in the urethra.

Prognosis.—This is favourable. Sometimes the disorder is cured before it becomes chronic; and dangerous complications are very uncommon.

Treatment.—The treatment of vaginitis in the acute stage consists in allaying irritation by rest in bed, warm baths, frequent injections of warm water, or warm but very weak, astringent solutions, and moderate purgation. The habits and health of the patient must be regulated, and all causes of excitement withdrawn. When congestion has subsided, stronger astringent injections should be efficiently applied, so that the whole mucous surface of the vagina, especially that of the cul-de-sac, is thoroughly laid. Alum or tannin should be applied in powder, by means of the speculum, to the deeper parts of the canal.

Complications.—The complications of gonorrhoeal vaginitis are various. Among the earliest is *catarrh*. The labia and clitoris grow red, swell, and a watery discharge is secreted. The patches of epithelium peel from the mucous surfaces, producing excoriation and occasionally ulceration of the mucous follicles. Usually, if the parts are kept clean, the irritation subsides in a few days.

Cretismus is the most constant accompaniment of gonorrhoea. Rarely so acute as to cause much irritation, it may produce severe suffering. It begins with itching and smarting at the meatus, which is red and swollen. A purulent or mucous discharge issues from the passage, unless the patient have just micturated, even then a little can be found in the mouths of two follicles which open close to the meatus. This discharge is very persistent, and is probably a source of contagion long after the disease is cured elsewhere. The treatment of urethritis consists of frequent baths, astringent injections, and cupping internally. Obstinate chronic discharges may be arrested by caustic solutions, carefully applied.

Acute inflammation of the cervix and os uteri is a frequent consequence of gonorrhoea. The neck of the uterus is swollen, red, and often excoriated about the os, whence a copious discharge issues, at first clear and viscid, then purulent. This subsides to a thin mucus, and either shortly ceases, or more commonly passes into chronic catarrhal flux, which lasts an indefinite time, and long retains its contagious quality. The acute inflammation is best treated by complete rest, warm baths, warm injections, and saline aperients. In the chronic stage its treatment is that of uterine catarrh.

Metritis, parametritis, and ovariitis may also result from gonorrhoea. See OVARY, Diseases of; and WOMEN, Diseases of. BECKLEY HILL.

GONORRHOEAL RHEUMATISM—An affection of the joints associated with gonorrhoea. See RHEUMATISM, GONORRHOEAL.

GOOSE-SKIN.—A condition of the skin in which this structure is rough and wrinkled, like that of the goose. It is of a transient character, being due to contraction of the muscular fibres of the skin, producing wrinkling of the integuments, and prominence of the hair-follicles, and is observed as the result of the direct application of cold, or of a shock, and in the early stages of fevers.

GOUT (*gutta*, a drop).—SYNON: Podagra, Chiragra, Goniagra (when the disease affects the foot, hand, or knee respectively); Fr. *Goutte*, Ger. *Gicht*. The name *gout* is supposed to have originated in the idea of the dropping of a morbid fluid into the joints, and is of very ancient date.

DEFINITION.—Gout is a general or constitutional disease, probably depending upon the presence in the system of excess of uric acid, the complaint being, in fact, a manifestation of the *lithic* or *uric acid diathesis*, *lithaemia*, or *lithaemia*. It may be hereditary or acquired, and is characterised ordinarily by a peculiar inflammation of the joints—*articular* or *regular gout*, attended with the deposit of urates in their structures, affecting usually and especially the smaller joints, and at first more particularly the metatarsophalangeal articulation of the great toe, but afterwards extending to other joints. Similar deposits of urates may occur in other tissues in course of time; and certain organs of the body are liable to become the seat of functional disorders, or of pathological changes, during the progress of the disease—*non-articular* or *irregular gout*; while it is also often attended with general symptoms. Gout in the early part of its course is usually an *acute* affection, occurring in periodic attacks or 'fits'; but subsequently it tends to become more or less *chronic* and permanent, though even then generally presenting exacerbations from time to time. The gouty diathesis may, however, be present without giving rise to any joint-affection or other evident organic mischief.

ÆTIOLOGY AND PATHOLOGY.—The etiology and pathology of gout are intimately associated, and must be considered in their mutual relations; and there are certain definite points which require to be noticed in this connection.

1. It is necessary to determine the immediate *pathological causes* of the gouty diathesis and its accompanying phenomena. Many views have been advanced, but they all belong to either of two groups, namely, the *humoral* or *anti-humoral*, the former attributing the complaint to some morbid condition of the blood and secretions, the latter to some functional disorder or organic change affecting certain systems of the body, and especially the nervous, vascular, or digestive systems. Loss of nervous tone, atropho-neurosis, venous and capillary congestion, and plethora of the chylipoietic viscera, are among the conditions to which gout has thus been attributed. In the writer's opinion an essential element

in the development of gout consists in the presence of some special morbid agent in the system; and it is now almost universally admitted that this agent is *uric* or *lithic acid*, which accumulates in the body in abnormal quantity. A variable amount of this substance is being constantly formed in the system during the processes connected with nutrition, but within certain limits, which probably differ in different persons and under different circumstances, it is capable of being eliminated by the kidneys or of being destroyed, and only when the acid accumulates beyond such limits are the gouty phenomena developed. In short, gout may be regarded as a manifestation of the so-called *lithic acid diathesis*, *lithaemia*, or *lithaemia*. The acid exists in the body as urate of soda, and in the gouty diathesis this salt is present not only in the serum of the blood, but also in the fluid that diffuses from it into all the vascular and non-vascular structures of the body (Hence-Jones). There are several arguments in support of this view:—(1) Gout occurs under circumstances which are known to induce in various ways the presence of excess of uric acid in the system, and, further, the causes which are most liable to bring on a gouty paroxysm are those which temporarily increase this excess. (2) While in the blood of healthy persons the quantity of uric acid present is so minute that it cannot be detected by any ordinary tests, in gout this substance may be obtained from blood-serum even in a crystalline form, either before or during an acute attack in early cases, or at any time in chronic cases. It has also been found in the fluid contained in blebs raised by blisters, provided they are applied at a distance from the seat of any acute gouty inflammation, in inflammatory effusions in serous cavities; and in dropsical fluids such as ascites. (3) Along with these indications of the presence of excess of lithic acid in the system, during an attack of acute gout the *absolute* quantity discharged in the urine is considerably diminished, while in chronic cases of the disease it is habitually more or less deficient, and at times may be almost entirely absent. (4) Deposits of urates, especially of urate of soda, are formed in the joints and other structures in gout, and this is the only disease in which such formations are found. Every attack of gouty inflammation is attended with the deposit of urates in the affected tissues, but the quantity is not in proportion to its intensity and therefore cannot be merely the effect of such inflammation.

Assuming this view of the essential nature of the gouty diathesis to be correct, different theories are held to account for the excess of lithic acid in the system, and they are probably all more or less true in different cases, in some instances the accumulation being explicable in more ways than one. Undoubtedly uric acid is often *formed* in excess, so that it cannot be adequately got rid of by elimination or in any other way. This excessive formation occurs in many cases without giving rise to the phenomena of gout, because so long as the kidneys are in good condition, and the nutritive processes are satisfactorily carried on, the acid is eliminated or destroyed. Again, it is supposed that

lithic acid may undergo *imperfect oxidation and destruction* in the body. Both these disorders have been attributed by some writers to a supposed influence of the nervous system. Others attach considerable importance to hepatic derangements in the causation of gout, and here it may be remarked that a distinct connection has been traced in some instances between this complaint and diabetes. Furthermore, the presence of an *undue quantity of other acids* in the blood may in some instances account for lithæmia. If, from various causes, such as deficient action of the skin, excessive consumption of acids or acid producing food, or the formation of acids in undue quantity during the process of digestion, these acids are present in excess in the blood, from their greater affinity they combine with the alkalis in this fluid, and diminish the alkalinity of the blood serum, so that it is less able to hold uric acid or urate of soda in solution. *Deficient elimination* is an important cause of lithæmia, and is often associated with other causes. It has been proved experimentally that in birds, if the ureters are tied, uric acid is deposited all through the tissues, but especially in the kidneys. It has been suggested that in some cases of the gouty diathesis the kidneys are congenitally small, and therefore cannot properly excrete even a normal quantity of uric acid, but especially any excess of this substance. Functional disturbances of the kidneys are also liable temporarily to interfere with their eliminating power, being often associated with, and probably due to, excessive formation of urates, while in course of time these organs become the seat of serious organic mischief in gouty cases, which gravely limits their excretory power, and in extreme cases arrests it entirely.

2. We are now in a position to discuss the circumstances under which the gouty diathesis is developed, and the more obvious *causes* with which this condition is associated. There are certain causes which may be regarded as more or less *producing*, and these will be subsequently considered, but ætiologically causes of gout may be conveniently arranged into three main groups, according as the disease arises from:—*a. Hereditary transmission.* *b. Certain errors in regard to food and drink, often associated with deficient exercise.* *c. Impregnation of the system with lead.* In not a few instances, however, it must be remembered that these causes are more or less combined.

a. Hereditary transmission. Gout is one of the most striking examples of a hereditary disease, and once established, it may be transmitted for several generations, even when every endeavour is made to eradicate it, but as the contrary is generally the case, the malady being as a rule more or less intensified by pernicious habits, it becomes in most cases a permanent legacy, handed down from one generation to another. Garrod found that in more than half his cases hereditary taint could be traced distinctly; and the proportion is much greater in the upper classes. It sometimes happens that when gout becomes developed *de novo* in an individual, children born previously are free from the complaint, while those born subsequently are liable

to be affected. Hereditary influences may be so powerful that gout arises without any other cause whatever; but most commonly this is aided by indulgence in certain habits to be presently mentioned, perhaps not to an extent which would be considered excessive for people in general, but which is excessive for persons predisposed to gout. This complaint sometimes exemplifies the so-called 'law of atavism,' but this is usually due to the fact that in the generation free from gout every precaution is taken to avoid causes which tend to originate a gouty paroxysm, these precautions being subsequently neglected. The hereditary nature of gout is shown not infrequently in the agent which the disease reveals itself. Should the predisposition be powerful, the complaint may appear even in children; and the younger the subject who is attacked with gout, the more likely is there to be an hereditary taint. The explanation of the transmission of gout in this manner is a mere matter of theory, and the excess of uric acid in the system has been accounted for in all the ways already mentioned.

b. Errors relating to food, drink, and exercise. In a considerable number of cases gout is originated *de novo*, in consequence of certain errors affecting the diet and habits, or an inherited tendency to the disease is considerably aggravated and promoted in this way. In general terms these errors may be summed up as excessive eating, especially of particular articles of food; undue indulgence in alcoholic drinks; and indolent habits, with deficient exercise. They are frequently associated in the production of gout, and not a few persons who eat and drink to excess, are saved from becoming gouty because they are of active habits, work hard, and take a considerable amount of exercise.

Although all kinds of food may assist more or less in developing the gouty diathesis, those elements which are rich in nitrogen are most injurious, and especially meat. Beef is believed by many to be particularly baneful. The writer has heard vegetarians affirm that meat is the great cause of gout, and that it never occurs when a vegetable diet is adhered to, but for such a statement there is no adequate proof. At the same time it must be acknowledged that this complaint is often in no small degree attributable to the amount of meat which is consumed. Many articles of diet, either from their own nature, or from the manner in which they are cooked, may help in the production of gout, by giving rise to digestive disorders.

The relation of intemperance in the use of alcoholic drinks to the gouty diathesis is highly important, and is abundantly proved by everyday experience. The more potent wines have the greatest influence in causing gout, and port wine has proverbially been regarded as the most injurious of all. Burgundy, madeira, sherry, and marsala are also undoubtedly capable of developing gout, or of keeping up the disease. The lighter wines are much less injurious, but champagne, and especially sweet champagne, certainly often promotes the gouty condition. Hock, sauternes, moselle, and light claret seem to be least injurious, but even these, if indulged in to excess, may in course of time set up, or, at any rate, intensify the gouty di-

these. Malt-liquors stand next to wines as originators of gout, and undoubtedly those who partake very freely of this class of alcoholic beverages are not uncommonly affected. In this way the disease may be usually accounted for when it occurs among the labouring and poorer classes, but it must be remembered that in these persons an inherited tendency to the complaint may exist. Brewer's draymen especially drink large quantities of ale or porter, and the writer has met with instances in which the habitual daily consumption has been acknowledged as averaging from two to four gallons. Spirits are comparatively feeble in their power of producing gout, as is proved by the rarity of the disease in those countries where this class of drinks are chiefly used, such as Scotland. Rum is said to form an exception to this statement. Cider and perry may unquestionably set up gout, if taken to excess, but they are much more powerful when sweet and not properly fermented. Excessive indulgence in a mixture of alcoholic drinks is probably more deleterious than if one is adhered to. The explanation of the differences in the tendency to develop gout exhibited by the various kinds of beverages is not very clear. They do not depend directly upon the amount of alcohol which they severally contain, but the admixture of certain other ingredients with the alcohol renders it far more potent in producing this effect, and the more alcohol then present, the greater is the likelihood of gout being originated. It is not, however, definitely known what those ingredients really are. At the same time it may be affirmed, as regards wines, that their quality has much to do with their tendency to induce gout. Facitious wines and others of inferior quality, as well as those which are very sweet or which contain much tannin, are most liable to produce this complaint. Drinks which cause a marked diuretic action are less capable of inducing the gouty state than those which have but little of such an action.

The modes in which the errors as regards food and drink induce lithæmia are probably various. They often directly lead to the formation of excess of nitrogenous products, and especially of uric acid, more than can be eliminated or destroyed in the system. Again, over-eating and drinking frequently cause undue production of other acids during digestion which take the place of uric acid, and prevent its elimination. Moreover, these habits disorder the digestive functions, cause congestion of the chylipoietic viscera, interfere with the hepatic functions, and ultimately set up a permanent dyspeptic condition, all of which assist in the development of the gouty diathesis. It has been supposed that indigestion from any cause might originate this condition, but according to the writer's experience this is certainly not the case. Persons who are hereditarily gouty often suffer from dyspepsia, but the disease may appear in such individuals when digestion has always been carried on without the slightest discomfort. Those who indulge in the habits which originate gout *de novo* are generally dyspeptic, as the result of these very habits. See Diet.

With respect to deficient exercise, this un-

doubtedly promotes the development of gout in many cases. Persons who follow sedentary occupations, or who live indolent and lazy lives, are certainly more liable to the disease, and not a few become gouty because they are able to 'keep a carriage,' and thus are deprived of the exercise which they were previously accustomed to take. This cause probably acts by limiting the conversion of uric acid into other waste products, which can be more easily got rid of; and also by increasing dyspepsia, in consequence of the organs which are concerned in the process of digestion doing their work slowly and imperfectly.

c. Another group of cases of gout which originate *de novo*, are those which occur in connection with lead-impregnation of the system. Dr Garrod found among his hospital patients, that about 30 per cent of those suffering from gout had been subjected to the influence of lead in their various occupations, and in the writer's experience, not only has the relation between lead-poisoning and gout been frequently exemplified, but some of the worst cases of this disease in its chronic forms occurred in persons who were distinctly under the influence of lead. This metal does not appear, however, to originate the gouty diathesis, unless aided by more or less indulgence in alcoholic drinks, though the amount of the latter consumed is usually far less than would alone account for the condition. It has also been found that gouty persons are remarkably susceptible to the influence of lead, and that when this metal is given to such persons for medicinal purposes, it is very liable to bring on a severe attack of acute gout. Garrod's observations seem to show that lead acts by diminishing the excretion of uric acid by the kidneys, and this authority states that the blood of individuals suffering from lead paralysis always contains an abnormal amount of uric acid, and that the same probably holds good in all cases of lead-chole.

3. Predisposing causes. — It is next requisite to notice briefly the predisposing causes of gout. Beginning with age, distinct gouty attacks in a large majority of cases make their first appearance in persons between thirty and thirty-five or forty years old. Those which occur under thirty are, with rare exceptions, more or less hereditary. Well-marked gout is exceedingly rare under twenty, but it may occur even in children, being then, however, invariably strongly hereditary. The complaint usually appears before fifty, and becomes progressively less frequent in its manifestation for the first time after this period of life. It is quite exceptional for gout to commence after sixty-five, but it may begin even in extreme old age. The cases in which the disease is developed during or after middle life mainly originate *de novo*, and one of the reasons assigned for the less frequent appearance of the complaint as age advances is, that then people usually become more careful in their mode of living, and more temperate in their habits. With regard to sex, males are far more commonly the subjects of well marked gout than females. This is mainly accounted for by the difference in the habits of the two sexes. It has also been partly attributed to the occurrence of menstruation in females, which acts to some extent as a safeguard, and in these

subjects gout generally appears after the cessation of this function. When strongly hereditary, gout may appear even in young females, of which the writer has seen some well-marked examples.

Ready conformation and temperament have been credited with a predisposing influence, persons of a sanguine temperament, and of corpulent, full-blooded, plethoric habit of body, being supposed to be most subject to this disease, and to have it in its most acute form. These conditions are often produced by the very habits which originate gout, and certainly persons who are gouty by inheritance often do not present any of these characteristics, while those presenting marked contrasts in appearance and temperament seem to be equally the subjects of the complaint. It is not uncommon in individuals of a nervous temperament, thin and wiry in frame, and they are said to be more subject to the irregular and asthenic forms of the disease. *Social position and occupation* materially influence the occurrence of gout. Formerly the complaint was met with almost entirely among the higher classes, and it was looked upon as an aristocratic disease. Now, however, it is common enough among the middle classes, chiefly those who are in affluent circumstances; while there are several occupations in connection with which the disease is very prevalent, such as butchers, coachmen, butchers, publicans and barmen, coal-heavers, porters, hair-cutters, and painters, or others who have to do with lead. It was at one time believed that high mental endowments predisposed to gout, this was obviously a mistake, although excessive mental labour, prolonged worry, and other causes which exhaust and depress the nervous system, do seem to predispose to the disease. As regards *climate*, those climates which are cold or temperate, and especially at the same time damp and changeable, present by far the greatest number of cases of gout, and in most tropical countries this complaint is unknown. This depends partly upon the differences in the nature and amount of the alcoholic drinks employed, partly upon the effect of climate as regards the functions of the skin.

4. Thus far we have been concerned with the pathology and aetiology of the *gouty diathesis*. Now we have to discuss briefly these points in relation to the *local manifestations of the disease*, and especially to the occurrence of *acute attacks*. Although the presence of excess of uric acid in the system is an essential element in the pathology of gout, such excess is often present, and yet none of its more characteristic phenomena are observed. An individual in this condition is, however, at any time liable to an attack of distinct gout, from the action of certain causes which would have no such effect upon other persons. If from any cause the amount of lithic acid in the blood is suddenly or rapidly increased, an acute attack of articular gout may be expected, or some internal manifestation of the disease. This is believed to be directly due to the action of the urate upon the tissues of the joint, which is supported by the fact that even after the first attack a distinct deposit of lithates is found in them, which increases with each subsequent attack. Two views are held as to the explana-

tion of its mode of action. According to one view the urate merely acts as a local irritant, it being supposed that different morbid agents in the system affect different tissues, and that this one acts specially upon the structures which are found in joints, setting up an inflammatory process. The degree of inflammation is, however, by no means in proportion to the amount of lithates which are deposited; indeed, the contrary is usually the case, for as a case of gout becomes more and more chronic, the deposit often becomes very abundant, though the paroxysms progressively diminish in intensity; while it is often found in other structures besides those connected with articulations, without causing any evident inflammation. The second view is that the acute paroxysm is the result of an attempt on the part of the articular structures to eliminate the morbid material, a chemical process of oxidation being set up in the parts where urates are most able or liable to accumulate, by which they are converted into uric acid, carbonates, &c., and so got rid of. This process gives rise to congestion, followed by inflammation and its attendant phenomena. It has been proved that the inflammatory process does destroy the urate in the blood of the affected parts, and probably the milt which has actually been thrown out is also partly destroyed. No uric acid can be detected in the fluid of a blister placed directly over an articulation which is the seat of acute gout. According to this theory the gouty paroxysm is to some degree salutary, as it helps to get rid of the excess of uric acid in the system.

It is a well known fact that gout tends specially to attack the smaller joints, and above all the metatarsophalangeal joint of the great toe, which is the one usually first affected. This is explained in the following way: in gout it is believed that those tissues are chiefly attacked which are either non-vascular, or which are supplied with but few vessels, and through which the fluids pass with difficulty, especially cartilaginous, fibrous, and ligamentous tissues. Such tissues are found in large proportion in the smaller joints. These are also distant from the centre of circulation, and the blood passes through them in a comparatively feeble and languid stream. They are, moreover, much exposed to the influence of cold and wet. And, lastly, with reference to the metatarsophalangeal joint of the great toe more particularly, this joint is peculiarly liable to injury from pressure, supporting the weight of the body, sudden shocks, &c. Another point observed in the history of gout is, that during an acute paroxysm several joints are often attacked in succession, while the inflammation subsides in those first affected, often with striking suddenness. This is accounted for by the deposit of urates in different joints successively, and when inflammation is thus excited in them, it tends to subside in those previously affected. Not uncommonly corresponding joints on opposite sides of the body are implicated alternately, probably through their nervous connection in the spinal cord. As gout advances in its progress, the articulations become more and more involved with each attack, because those first involved become, as it were, saturated with urates, and

therefore new tissues of the same class are involved.

An acute paroxysm of gout may come on without any evident exciting cause whatever, especially if the disease is strongly hereditary, or has been long established. Under these circumstances outbreaks of the complaint seem to become habitual at certain seasons, or they arise from very slight causes, which need to be less and less obvious as the case progresses. Often, however, some distinct exciting cause can be made out, affecting the digestive organs, the vascular or nervous systems, the functions of the skin or kidneys, or disturbing the system in other ways. The most important are eating or drinking too much, either on some particular occasion, or habitually for a longer or shorter period, until at last a fit of gout terminates the indulgence, it being borne in mind that even apparent moderation may be excessive for a gouty person. Indigestible articles of food, neglect of the act of defecation, or constipation; undue physical work or exertion; exposure to cold or wet, or suppression of perspiration; excessive mental work or worry, emotional causes, sudden, powerful, or depressing, such as sudden joy a fit of rage, or deep grief, hemorrhage, acute illness, or other debilitating causes, or injury. The implication of a particular joint may be also due to injury, which may be very slight, such as the pressure of a boot, or the toe being trodden upon. Injury to the knee has caused that articulation to be first affected. As *predisposing causes* of acute gouty attacks, climate and season are highly important. Their characteristics have already been indicated, and undoubtedly gouty paroxysms may often be averted by residence in a warm climate, either permanently or during the colder seasons of the year. Early attacks seem to be most frequent in the spring; then they occur also in the autumn; and subsequently they become more frequent and irregular in their onset. One seizure predisposes to another, and it is a special feature of gout that it tends to recur, this tendency increasing with each succeeding paroxysm, until finally, in many cases, the patient cannot be said to be ever free from the complaint. The occupation of an individual may predispose to the occurrence of gout in particular joints, thus butlers have it in the feet, coachmen and washerwomen in the hands.

It is found in process of time that gouty concretions form in other parts besides in the joints. This is easily explained by the fact that urates tend to deposit in certain other structures which are but slightly vascular, besides those forming part of the articulations. Vascular tissues seem to destroy urates in their passage through them, and thus they are prevented from doing any harm to these tissues. The presence of urates in the blood will account, not only for the chronic gouty state, but also for acute attacks affecting internal organs, or so-called irregular gout. It has been maintained that the development of gout in other structures besides the joints is influenced by the diathesis and habits of the individual, but it is doubtful how far this is borne out by actual experience.

ANATOMICAL CHARACTER.—In its most typical

manifestations gout is characterised anatomically by the occurrence of a peculiar form of inflammation affecting certain joints, this being invariably attended with the deposit of urate in connection with their structures. Taking an individual articulation, this is at first the seat of an acute inflammatory process, indicated by the usual signs of increased vascularity and redness, tumefaction, and serous effusion into the interior of the joint, as well as into the surrounding tissues. The results of post-mortem examination show that even in the very earliest period a deposit of urate takes place, and as the attacks become repeated again and again, the signs of inflammation become less and less prominent, while the deposit increases, until at last it may form considerable masses, and infiltrate extensively all the structures entering into the formation of the articulation. The joint then becomes permanently enlarged and distorted, while the ligaments are thickened and more or less stiff or quite rigid, and ultimately complete ankylosis may be produced. The deposit seems to commence in the substance of the cartilage covering the ends of the bones, starting near its superficial or free surface, and gradually extending more deeply, though for a time a thin layer of cartilage lies between it and the cavity of the joint. This deposit at first forms a whitish opacity, but as it becomes more abundant it encrusts the cartilages, and also the inner surface of the ligaments, and the surfaces of fibro-cartilages where these exist. More or less extensive spots or patches become in time distinctly visible, and even the entire surfaces of the bones forming a joint may be covered with a chalky-looking substance. The synovial membrane may also present white points, but the synovial fringes at their margins seem to escape, on account of their vascularity. In the larger articulations the synovial fluid may be thickened, and may even contain separate crystals or tufts of the urate. Subsequently the ligaments and adjoining structures are infiltrated and it is to this cause that the stiffness or rigidity of gouty joints is mainly due. Distinct masses of deposit may, however, form, and these also interfere with movement. They are known as *tophi* or *chalk-stones*. In course of time the tissues covering a gouty joint may be destroyed, including the skin, the chalky-looking substance being thus exposed, and unhealthy suppuration and ulceration set up.

The opaque white substance characteristic of gouty inflammation is found on microscopic examination to consist of fine crystals, in the form of needles or prisms. They are chiefly arranged in minute clusters, radiating from a centre; and in the cartilages they form a more or less compact network. Chemical examination shows that they are composed of urate of soda.

With reference to the joints which are affected in gout, as has been already indicated, the metatarsophalangeal articulation of the great toe is the one primarily attacked in a large majority of cases. In rare instances, where an opportunity has been afforded of making a post-mortem examination after only one or two gouty fits have occurred, this joint, on one or both sides, has alone presented any change, even after many years have elapsed since the occurrence of the

attacks. As usually seen, however, the disease has progressively involved many joints. In the feet it may implicate all the articulations, but it is a curious fact that the tarso-metatarsal and the phalangeal joints of the great toe generally escape, or are but little affected. Similarly all the joints of the hands and fingers are often involved. The gouty change not uncommonly extends to the larger joints, more especially those of the legs, but the shoulder and hip-joints are but little liable to be attacked. In exceptional cases other articulations are found involved, such as the temporo-maxillary, those of the spinal column, of the pelvis, or even of the larynx.

Coming now to other structures, deposits of urate may occur in various parts of the body, in connection with bursae, tendons and aponeuroses, sheaths of muscles, the sclerotic coat of the eye, the cartilages of the external ear, eyelids, nose, or larynx, or under the skin. More or less effusion may be present in bursae at the same time. In a case which came under the writer's notice, and in which there was not the slightest hereditary taint, in addition to numerous *tophi* in the auricles, there was a mass in the bursa over the right olecranon as large as an egg, a smaller one over the left elbow, several distinct deposits over both patellae, and others in connection with the tendons of the hands, especially the right.

As regards bone, the periosteum is often affected and some writers have described a deposit of urate in bone itself, but Garrod has not found evidence of its having originated in this tissue. He considers that the periosteal formations sometimes acquire sufficient size to press on the osseous tissue, and to cause its absorption.

The condition of the kidneys induced by the gouty diathesis is of great importance, and these organs probably begin to be diseased at a very early period in the history of a case of gout, for they may be found distinctly affected when there have been little or no external manifestations of the complaint. In the first instance a deposit of urate of soda takes place, probably within the renal tubuli, which afterwards involves their walls and penetrates to the intertubular tissue. This is seen in the form of white streaks in the coats of the tubuli, and of white points at the extremities of the papillae. The deposit goes on increasing and a chronic inflammatory process is set up, ending ultimately in the production of the 'granular contracted kidney' (see BRIGHT'S DISEASE). Other morbid states in connection with the urinary organs observed in some cases of gout are the presence of calculi, consisting of uric acid, urate, or oxalates, chronic cystitis; or urethritis.

In the course of gout morbid changes of other kinds often arise, affecting different structures and organs, and either occurring as acute events, which may even prove fatal, or being of a chronic nature. These need be only mentioned here, and they mainly include congestion, catarrh, or severe inflammation of some part of the alimentary canal; catarrh of the air-passages, chronic bronchitis, and emphysema of the lungs; fatty disease of the liver; meningitis, neuritis, cerebral hæmorrhage;

cardiac changes, including chronic valvulitis and degeneration of the valves, and hypertrophy, followed by degeneration, of the cardiac walls; atheromatous changes in the vessels, hypertrophy of the muscular coat of the small arteries, or arterio-capillary fibrosis; and various diseases of the skin, such as erythema, urticaria, eczema, psoriasis, &c. How far some of these conditions can be attributed to the gouty diathesis, or are merely the result of the same causes which have induced this diathesis, may be fairly disputed. It is worthy of remark that acute inflammation in connection with the heart is not met with in cases of gout, and this has been attributed to the great vascularity of the endocardium and other cardiac tissues, for which consequently the urate has no affinity, or it is destroyed in its passage through them.

The condition of the blood in gout may be here noticed. In early cases the chief deviation from the healthy state presented by this fluid is that during the acute paroxysms the serum contains a distinct excess of uric acid, in the form of urate of soda, and this can be obtained in appreciable quantity, even in a crystalline form. In the intervals the blood is quite normal. When the gouty condition becomes chronic, the excess of uric acid is constant, and oxalic acid can also be frequently detected. In course of time the serum becomes lowered in its specific gravity, its albumen is deficient, and its reaction is less alkaline, in extreme cases becoming almost neutral, owing to the presence of excess of acids. When the kidneys are implicated, uræa also tends to accumulate in the blood, and may be obtained in variable quantity. The red corpuscles often diminish in number; and the blood deteriorates in quality as a whole in many cases of chronic gout.

SYMPTOMS.—The clinical history of gout is a very varied one, and the symptoms observed in different cases which are regarded as of a gouty nature are exceedingly numerous and diverse. Whether the phenomena attributed to this disease are always fairly explicable by the presence of excess of uric acid in the system is, to say the least, a matter of considerable doubt. It must ever be borne in mind that the habits which generate gout often give rise to symptoms, and even to definite morbid changes, which cannot justly be looked upon as part of this complaint. Again, the custom which some practitioners adopt, of looking upon every acute illness, particularly inflammation of organs, occurring in gouty subjects, as being due to the lithæmic condition, and of a special nature, and applying the term 'gouty' to every such complaint, is certainly going too far, though it may be acknowledged that gout does often modify their clinical history. It is not easy within a limited space to give even a sketch of the various clinical phases of gout, but before considering the symptoms in detail, it may be well to indicate their general nature. 1. In its typical form gout is in its early stages attended with acute symptoms referable to certain joints, and these tend to recur at intervals, constituting 'fits of gout,' the intervening periods becoming shorter and shorter as the case progresses.—*Acute Articular or Regular Gout.* 2. These attacks

disturbance in obvious chronic changes in the affected joints, with corresponding symptoms—*Chronic Articular Gout*—but even then acute paroxysms are liable to arise from time to time. 3. In connection with the acute attacks, and sometimes preceding them, *general or constitutional* symptoms are usually observed; and symptoms belonging to this class become permanent in most cases of chronic gout. 4. When gout affects other organs and structures besides the joints, corresponding symptoms are developed according to the part implicated. In general terms these may be grouped as cases of so-called *Non-articular, Irregular, Mispaced, or Anomalous Gout*; and when such symptoms are acute in their character, affecting some internal organ, and coming on during the course of an attack of acute articular gout, the joint-symptoms at the same time subsiding, this constitutes what is termed *Recurrent gout*. It is supposed to be due to exposure to cold or other causes checking the articular inflammation, the elimination of uric acid being thus interrupted so that it accumulates in the system. The symptoms thus grouped together may, however, be conveniently subdivided as follows:—(a) Those in which more or less functional disorder of certain organs, varying much in intensity, and either being constantly present, or only coming on at intervals. (b) Those due to acute inflammatory affections of organs. (c) Those resulting from the chronic changes in tissues and organs induced by gout, and from the deposit of urates in different parts. Having given this outline, we may now discuss the symptoms of gout in some detail, but it will be convenient in doing so to adopt a somewhat different arrangement from that just sketched.

1. **Premonitory Symptoms**—There are certain symptoms, of a somewhat indefinite character, and not of any marked intensity, which are often met with in gouty subjects, or even in persons who have never actually suffered from declared gout, but which distinctly depend upon the lithemic condition. These may be regarded as premonitory symptoms, for they frequently give warning that the gouty condition is in process of development, and if duly recognised, enable the patient so to regulate his mode of living as to ward off the disease. Indeed, it will be found on careful inquiry that gouty phenomena, which may be very marked, are commonly noticed from time to time before the first actual fit of gout occurs, and there may even be suspicious twinges or uncomfortable sensations about the toes or fingers now and then. In a large number of cases, however, no definite premonitory symptoms immediately precede the first gouty paroxysm; but in connection with subsequent paroxysms, prodromata are usually marked, so that confirmed gouty patients can predict when an attack is imminent. As to the nature of these symptoms, they vary in different persons, and this is supposed to depend upon individual predisposition. The most obvious are digestive and hepatic disorders, attended with marked flatulence and eructations, heartburn, acidity, and constipation or diarrhoea, with unhealthy stools, the tongue being often large, flabby, and much furred; palpitation or uncomfortable sensations about the heart; catarrh of the throat and respiratory

passages, violent fits of sneezing, or asthmatic attacks, derangements of the nervous system, indicated by a liability to headaches, giddiness, noises in the ears, disorders of vision, marked irritability of temper and fretfulness or lowness of spirits, languor, impairment of mental vigour and intellectual hebetude, heaviness or drowsiness, sleep, however, being restless, disturbed, attended with unpleasant dreams, and often with grinding of the teeth, numbness or tingling in the limbs, especially in the fingers or toes, neuralgia in various parts, twittings, startings in the limbs, or muscular cramps, especially in the calves of the legs; profuse perspirations; certain skin-affections; and changes in the urine. This excretion usually tends to become high-coloured, deficient, and to deposit lithates abundantly, or even lithic acid crystals, though at the same time the quantity of this acid eliminated within the twenty-four hours is below the normal. In advanced cases of gout, however, the urine presents very different characters from those just stated, as will be hereafter pointed out, and when habitually depositing urates, it may become pale, watery, and clear immediately before an acute attack supervenes. Some patients are warned of the approach of a gouty fit by feeling unusually well, both physically and mentally.

2. **Acute Articular Gout**—It is only with the occurrence of the first acute attack of gout that the disease is usually regarded as established. The paroxysm as a rule comes on during the night, while the patient is asleep in bed, and it is said to commence usually between 2 and 5 a.m. The patient is disturbed out of his sleep by uneasiness or pain, generally referred to the ball of the great toe on one side, and the corresponding joint is found to be inflamed, the inflammation increasing in intensity, until it usually becomes extremely severe. In some instances the corresponding joints on both sides are attacked simultaneously, in rapid succession, or alternately. Although however, in the majority of cases gout first attacks the metatarsophalangeal articulation of the great toe, it must not be forgotten that it may start in any of the smaller joints of the foot or hand, or even in the middle-sized joints, especially the knee or ankle. Indeed, exceptional cases have come under the writer's notice, which there was every reason to believe were of a gouty nature, and in which the disease implicated several joints at a very early period of its course, the feet, however, being free. In such instances it may be that there is a true combination of rheumatism and gout.

Proceeding now to notice the clinical characters of the joint-affection, severity of the pain is certainly a striking feature in the majority of cases of acute gout, especially in early attacks. When the foot is affected, any attempt to stand causes much pain from the first, and the suffering speedily increases, until it becomes very intense, in some instances almost unbearable. In character it varies, and is described in different cases as burning, throbbing, aching, tearing, plunging, boring, piercing, &c. The pain prevents sleep during the night, but towards morning it tends to diminish, and during the day there is usually comparative ease, an exacerbation

tion again taking place as evening approaches, which goes on increasing towards night. Tenderness is very marked, and is often so exquisite that the patient dreads to be touched, and cannot bear the least movement or jarring of the affected part, or sometimes even the weight of the bedclothes, or the slightest shaking of the room. The objective signs of inflammation in connection with a gouty joint also soon become very prominent as a rule. These are marked redness, which may be very deep and sometimes tends to lividity, while the veins are often enlarged and turgid, considerable local heat, as evidenced to the touch and by the thermometer; and much swelling, the skin covering the part assuming a tense and shining appearance, or even a considerable extent of the limb being oedematous. When several joints in the foot or hand are affected, diffused redness and swelling are noticed. The tumescence is not only due to effusion into the interior of the articulation, but also into the surrounding tissues, oedema being a marked feature in connection with gouty inflammation. This can be better appreciated when the acute symptoms subside, so that pressure can be borne, which shows the pitting characteristic of oedema, and this may hold on for some time after the other signs have disappeared. However intense the objective signs of inflammation may be, acute gout never ends in suppuration. As they subside, marked desquamation of the skin usually takes place, which is partly due to the intensity of the inflammation, partly to the oedema, the vitality of the epithelium being thus destroyed. As the swelling increases, the subjective sensations generally diminish in severity; but during the progress towards recovery, intense itching is apt to supervene.

An acute attack of gout is almost always attended with more or less *general* symptoms, but it is an important fact that their severity depends upon the extent and intensity of the local manifestations of the disease, and upon the accompanying symptoms. Chills or even actual rigors may be felt at the outset, followed by febrile phenomena, sometimes slight, in other cases considerable, the pyrexia being as a rule strictly secondary or symptomatic. The skin feels hot, and usually perspires, but not profusely; the temperature is moderately raised, presenting no definite variations, though marked remissions are generally observed towards morning, the pulse is increased in frequency; and the digestive organs are much disordered, as evidenced by anorexia, thirst, furred tongue, and constipation. The urine is generally deficient in quantity, and may be very scanty, high-coloured, and concentrated; its acidity is increased; and on standing an abundant deposit of amorphous lithates often forms, varying in colour according to circumstances, being pale-buff, yellowish-red, dark or brick-red, or intense pink if the fever is high. The relative quantity of uric acid in a particular specimen of urine is often increased, but the absolute amount discharged within the twenty-four hours is much diminished. The patient is usually exceedingly restless, and cannot lie with comfort in any position; sleep is much disturbed or altogether

prevented; and cramps of the calves of the legs or of other muscles may still further increase his sufferings. All these symptoms tend to increase the constitutional disorder. The temper is generally very irritable, or may even be violent.

The duration of the first fit of gout varies according to circumstances, such as the severity of the attack, the diet and regimen adopted, and probably the kind of treatment which is employed. It usually ranges from four or five days to a week or ten days, but may last two or three weeks or more, there being then commonly intermissions or remissions, and several joints being involved in succession. The termination of the gouty paroxysm may be attended with critical phenomena, such as free perspiration, diarrhoea, or a very abundant discharge of urates. After the attack the patient may not recover his former state of health for some time; but not uncommonly he feels better than before, and as if the system had got rid of some deleterious element. As a rule the affected joints are apparently quite restored after early attacks of gout; but it must be remembered that even after a single fit they are the seat of permanent morbid changes, and these may be distinctly evidenced by more or less deformity or stiffness. Oedema may also remain for a considerable time, especially if the inflammatory condition has been prolonged.

One of the characteristic features of gout is the tendency which it exhibits to recurrence in its acute form. This may not happen if the patient is sufficiently careful, but such an event is of rare occurrence. The rule is for the attacks to be repeated, and to recur with ever-increasing frequency. In not a few instances the second fit does not occur until an interval of two or three years or more has elapsed, but in most this is not prolonged beyond a year. The same interval may be noticed between the next few paroxysms, but as the disease progresses they return twice a year, then more frequently, and at last become more or less constant. At the same time the mischief extends as regards the joints. It may be limited to the great toe for some time, but in successive fits spreads to the other articulations of the foot, to the hands, the ankles and knees, the wrists and elbows, and occasionally even to the hips and shoulders. In short, gout tends in time to involve nearly all the joints indiscriminately, and several may be implicated during a fit. Moreover, those articulations which are repeatedly attacked become more and more disabled and deformed, until a condition of chronic gout is set up. The symptoms in connection with a particular joint tend to diminish in intensity the more often it is affected. As additional articulations become involved, however—and many may be implicated at the same time—the general symptoms often increase in severity, and the patient does not recover in the intervals. The duration of the attacks becomes longer as their frequency increases. The rapidity of the progress of gout is very different in different cases; and the time taken to produce permanent mischief in the joints varies considerably.

It must be borne in mind that variations in the intensity and exact characters of the symptoms of acute gout are observed in some cases.

In feeble persons the subjective and objective symptoms may be comparatively slight, the inflammation assuming an asthenic character, but then the ultimate effects upon the joints are often much worse. Again, the pain in connection with a particular joint depends considerably on its structure, being usually much more marked if its ligaments, or the parts around, are rigid and unyielding. Previous injury or disease affecting a joint may likewise modify the symptoms. Some individuals suffer much more than others, being more susceptible of painful impressions.

3. **Chronic Articular Gout.**—In course of time more and more of the joints become permanently and obviously changed, and prevented from fulfilling their functions properly, so that a condition of chronic articular gout is established, exacerbations still occurring, however—included with much greater frequency—but being much less acute in their intensity than in the early stages of the disease, and longer in duration. It need hardly be remarked that there is no distinct line of demarcation between acute and chronic gout. The hands are particularly liable to be much altered by the effects of gouty inflammation. The permanent changes are indicated by the articulations becoming enlarged, deformed, and irregular in shape, often presenting nodulations or bulgings, which may attain a large size, owing to the abundance of the deposited urates. They are also stiff and crippled in their movements, at last becoming quite immovable and rigid, or even completely ankylosed, and being either permanently flexed, extended, or sometimes even bent backwards. The interference with movement and the deformity do not bear any necessary proportion to each other, the one or the other predominating according to the mode in which the deposit of urate of soda has taken place. The more this infiltrates the ligaments and surrounding tendons, the greater becomes the impediment to movement. Gouty concretions in connection with joints feel hard, and by their mere mechanical and irritative effects they are liable to cause damage to the adjoining structures. They may be seen stretching or shining through the skin, and causing it to assume a bloodless appearance, or, on the other hand, rendering it congested and bluish, the veins also being enlarged. Ultimately a gouty abscess may form around the concretions, which opens externally; or the skin may merely give way from the continued pressure. Thus the *chalk-stones* are exposed, and come away either in a liquid form or as solid particles or masses, or occasionally there is a free discharge of pus as well. Ulcers are left, of an unhealthy and atonic character, and usually presenting no disposition to heal. There may be a number of these ulcers in the same individual, on the hands and feet. When bursæ are involved, much deformity is produced. They are easily felt, usually presenting a combination of hardness and fluctuation, due to the presence of concretions and of fluid in the bursal cavity. These signs are chiefly noticed in the bursa over the olecranon. Abscesses may also form in connection with these deposits, and the latter

may thus be completely got rid of, the abscess subsequently healing rapidly.

In cases of chronic articular gout the general system necessarily tends to become affected. The patients are generally more or less feeble and wanting in tone; they may be thin and pale or sallow-looking, or plethoric, but with flabby tissues, and presenting signs of languid circulation, with enlarged capillaries about the face. They often suffer from disorders of digestion and other symptoms already described, but not uncommonly, as gout assumes more chronic form, patients feel better, becoming habituated to the morbid condition of the blood. It is remarkable that those suffering from numerous gouty abscesses often exhibit but little general disturbance, probably because the system is thus rid of the morbid materials. The urine in chronic gout generally becomes abundant, very watery and pale, of low specific gravity, deficient in solid ingredients, especially in uric acid, which at times may be almost completely wanting, or it may be thrown out in an intermittent manner. Deposits of urates are not often observed in cases of advanced chronic gout, except perhaps before the occurrence of an acute exacerbation.

4. **Irregular Gout.**—The clinical phenomena which are recognised as irregular manifestations of gout may assume either an acute or chronic form. They may be observed in persons who are distinctly subject to articular gout; or in those in whom the disease is not so obviously revealed. Moreover, their intensity is often in an inverse ratio to that of the joint-affection, and the two classes of symptoms may exhibit a remarkable tendency to alternation, when the articular symptoms are prominent those connected with other parts being slight or absent, and *vice versa*. This may be noticed with both acute and chronic symptoms, and the former are particularly liable to arise when, from any cause, during the progress of a gouty fit the joint-inflammation is suppressed suddenly or rapidly—*retrocedent gout*. At other times the internal symptoms seem to be due to a want of development of the external phenomena—*suppressed gout*, and when the latter appear, the former subside.

It must suffice to indicate here the general nature of the symptoms of irregular gout. The acute symptoms are mainly associated either with the alimentary canal, the vascular system, the respiratory organs, or the nervous system. In connection with the alimentary canal, acute dysphagia may occur, attended with spasm of the pharynx and œsophagus. The most important symptoms belonging to this group are, however, those due to some gastric disturbance. This may be of the nature of severe cramp or gastralgia, characterised by a sudden, acute, spasmodic pain in the epigastrium, relieved by pressure, and accompanied with a sense of great weight and oppression; the patient presenting an aspect of much suffering, distress, and anxiety; or being even more or less collapsed and prostrated. In other cases the symptoms are those of acute gastritis, bilious vomiting being prominent. Intestinal colic, or even mucœ-enteritis, may also occur in connection with gout. The vascular system is not uncommonly implicated. The

heart is liable to be disturbed in its action during the attacks of gastralgia, but this disturbance may also be observed independently. It is usually of nervous origin, and may be evidenced in various ways. Thus there may be severe palpitation, the action of the heart being very rapid, irregular, or even intermittent, this being accompanied with most unpleasant sensations over the cardiac region, pre-cordial anxiety, often a feeling of oppression or constriction, dyspnea or a sense of suffocation, and much distress, anxiety, and dread of death, the pulse tends to be weak and small, or may be irregular, sometimes the attacks are attended with signs of collapse. In other instances the cardiac disorder is evidenced by very feeble or slow action, with a tendency to syncope. Again, there may be all the phenomena of a severe anginal attack, this probably partly depending upon the circulation in the vessels being impeded. It must be once more noted here that there is no true gouty acute inflammation connected with the heart, although certain chronic changes sometimes observed at *post-mortem* examinations have been attributed to such a condition. Irregular gout affecting the respiratory system is mainly indicated by asthmatic attacks. In some cases there is a marked liability to acute catarrh of the air-passages. Pulmonary congestion is also supposed to be a manifestation of reticent gout in some cases, but there is no such special disease as gouty pneumonia. In connection with the nervous system gout may give rise to attacks of severe headache, delirium or even acute mania, epileptiform fits, cerebral or spinal meningitis; acute neuralgia, either external or internal, and especially sciatica, probably due to neuritis, or severe muscular cramps. Apoplexy from cerebral hemorrhage has been often attributed to suppressed or retrocedent gout, and if the vessels of the brain are diseased, it is possible that there may be some connection between them. Cerebral congestion might also occur in gout, and give rise to a temporary apoplectic attack. Among the acute forms of irregular gout are, for example, skin-affections, eczema, erythema, or urticaria, affections of mucous membranes, such as the conjunctivæ and lachrymal passages, functional renal disorder, with albuminuria, or irritability of the bladder; and local signs of inflammation, associated with the deposit of urates.

Many of the more chronic symptoms associated with gout have already been pointed out, when speaking of its premonitory symptoms, and only certain phenomena need be alluded to here. Chronic skin diseases are of frequent occurrence, namely, psoriasis, chronic eczema, prurigo, either local or general, and acne. These may alternate very distinctly with articular gout, and they are often intensified by causes which increase the lithæmic condition. In some gouty subjects daily paroxysms of heat and redness of the nose, attended with severe itching and irritation, cause considerable annoyance or distress. Many of these individuals are also liable to chronic catarrh, affecting the throat and the air-passages; and in time they often become permanently asthmatic, the lungs being emphysematous, and dry bronchial catarrh

being established. Gravel or urinary calculus gives rise to symptoms referred to the urinary organs; and those indicative of chronic urethritis or cystitis may be present, especially in persons advanced in years. Permanent disorders of sensation, or slight local paralysis may be observed in gout, owing to chronic changes involving particular nerves. Gouty persons are usually very sensitive to pain. Tophi can be seen or felt, provided they are superficial. Those connected with the helix of the external ear are most common; but they should also be looked for in the sclerotic or eyelids, in the nose, and under the skin, in the region of tendinous aponeuroses, especially in the leg or thigh. The writer had the opportunity of observing a case in which an extensive formation of urates occurred in the outer part of the thigh, apparently associated with the *fascia lata*. These gouty concretions are originally liquid, and if one is punctured at an early period, an opalescent or milky fluid escapes, which on microscopic examination is found to contain an abundance of delicate, acicular crystals, subsequently they become more consistent, and ultimately quite solid and hard, being then made up entirely of these crystals, which are closely aggregated together and interlaced. Taking the ear as an illustration, at first a small elevation appears under the skin of the helix, like a vesicle, having a soft feel. This gradually hardens, until finally a little bead-like or pearl-like body is formed, presenting a whitish colour as seen through the skin. In course of time the cutaneous covering may be destroyed, leaving the little chalk-stone exposed, or this may even become detached, so that only a small depression is left.

5. Symptoms due to chronic organic diseases.—In addition to what has been stated under the preceding heading, it is desirable just to notice separately certain diseases of organs which may be associated with the gouty diathesis. Disease of the kidney is indicated mainly by the changes in the urine, which may be slightly albuminous, or even contain a few casts. Other symptoms of chronic Bright's disease may be present, but it must be remembered that in the form of renal disease associated with gout the symptoms are often very obscure. The chronic cardiac diseases observed in gout are revealed mainly by their respective physical signs; and there may be symptoms, first of excessive cardiac action from hypertrophy, and subsequently of cardiac failure. The vascular changes are evidenced by examination of the arteries; and by their effects upon the circulation. Fatty liver can only be discovered by physical examination.

DIAGNOSIS. The degree of difficulty experienced in arriving at a diagnosis with respect to gout, is very variable in different cases, whether in definitely fixing upon this disease, or in distinguishing it from other affections. Often the diagnosis is perfectly clear, but in some instances it may be extremely difficult to form a positive opinion. It must be remembered that there may be a distinct gouty diathesis present, and symptoms resulting therefrom may arise, which it is important to recognise, while the joints are quite free from any apparent mal-

chief. It is also desirable to be able to make out any tendency to the development of this diathesis. In most cases, however, the diagnosis has to deal with the nature of an articular affection, and to determine whether this is gouty or not. The chief diseases from which gout has thus to be distinguished are acute or chronic rheumatism, and rheumatoid arthritis. The data upon which a conclusion has usually to be formed with regard to a first attack, are the presence or absence of a hereditary tendency to gout, as well as its intensity; the age and sex of the patient; his social position, occupation, and previous habits; the presence or absence of any obvious cause for the attack, or of premonitory symptoms; the localisation and characters of the joint-affection; the general symptoms; the characters of the urine; the duration of the illness; and the condition of the heart. These different points have already been sufficiently discussed in their relation to gout, but the distinctions presented by acute rheumatism may be briefly indicated. The absence of any hereditary tendency to gout in any doubtful case may be in favour of rheumatism, and possibly this complaint may be hereditary. It occurs most frequently for the first time in early life, from sixteen to twenty years of age, and is not uncommon even in young children. Rheumatism, though more common among males, often attacks females. This complaint is not favoured by the habits which generate or promote gout, and affects all classes of persons, but especially those who from their occupation are liable to be exposed to cold and wet. Such exposure, or some other definite cause originating 'a cold,' usually accounts for an attack of acute rheumatism, and it is not preceded by any particular premonitory symptoms. The joints involved are the middle-sized or the larger ones, several of which are generally implicated in succession during the illness, the rheumatic inflammation exhibiting an erratic character, the local symptoms tend to be less severe than in gout; there is less marked oedema about the joints, and no enlargement of the veins or subsequent desquamation are observed. It must not be overlooked, however, that gout may attack the middle-sized joints. Pyrexia is high as a rule, and is often quite out of proportion to the extent of the articular affection, while profuse acid perspiration is almost always a prominent phenomenon. The urine is simply febrile. The attack lasts a considerable time, perhaps several weeks, if it is at all severe; while during its course some acute cardiac inflammation is liable to supervene and this may happen even when the joint-affection is but slight. The subsequent progress of gout is important in diagnosis, for its tendency to periodic recurrence is a marked feature in its history, and if the metatarso-phalangeal joint of the great toe is alone inflamed several times in succession, or even if only the smaller joints of the feet and hands are implicated, the diagnosis of gout is tolerably certain. The permanent articular changes induced by gout also become evident in time; as well as, perhaps, tophi in other parts, which should be carefully searched for in any doubtful case, especially in connection with the external ear, the nose, and bums. Moreover,

the urine presents peculiar changes as the disease progresses, and may give evidence of renal mischief. In very doubtful cases it might be desirable to raise a blister, or even to take a little blood from the patient, and endeavour to obtain crystals of uric acid from the serum.

Rheumatoid arthritis is usually met with in females between twenty and forty years old. There is no hereditary taint, or a history of any such habits as generate gout, but, on the contrary, the patients are generally poor, hard-worked, and badly-fed, and consequently weak and wanting in tone; all joints seem to be equally liable to be affected, both large and small, and the symptoms are not of a very acute character, though the pain may be very severe, but they tend to continue for a long period; the general symptoms are mainly those of debility and anæmia. Rheumatoid arthritis is a disease which tends to progress, involving joint after joint, but it presents no periodicity in its attacks, and often advances without any intermission, as a subacute or chronic disease. Ultimately it often causes much deformity and crippling of the articulations, but this results from a very different pathological change from that which takes place in gout, for there is not the slightest deposit of urates, either in the joints or elsewhere, nor in the most extreme cases can any uric acid be obtained from the serum. The urine presents no special characters; and the kidneys are not diseased.

As exceptional points bearing upon the diagnosis of gout in joints, the following may be mentioned. It has happened that pyæmia beginning in the great toe has been mistaken for gout, but the progress of the case would soon clear up any doubt under such circumstances. Again, articular inflammation from injury might resemble gout, and, moreover, it must be borne in mind that such an injury may really set up gouty inflammation for the first time, so that the joint may not recover properly. In some individuals the ends of the phalanges of the fingers are enlarged, especially terminal ones, and cause nodulations—*dactylorum nodi*—which resemble those of gout, and are by some regarded as being of a gouty nature.

The importance of recognising the signs of the gouty diathesis, apart from the joint-affection, has already been alluded to. Equally important is it to be prepared for the acute symptoms in connection with internal organs which occur in this diathesis, whether along with or independent of articular disease. Lastly, in any gouty case the detection of the organic diseases liable to be set up in its course is of great moment in diagnosis, especially renal disease, and also the association with their proper cause of cutaneous affections, skin-diseases, and other complaints, when these are due to gout.

Prognosis.—The first point relating to the prognosis of gout which calls for notice refers to the immediate dangers in any particular case. A simple acute attack of articular gout rarely, if ever, kills the patient. When, however, internal organs are implicated, the matter becomes much more serious, and a fatal result may occur, so that the prognosis must be a guarded one under such circumstances. The danger then becomes much greater if the complaint has been

long-established, and if the kidneys or other organs have become structurally diseased. Indeed these diseases of organs themselves are attended with grave dangers, and may give rise to fatal consequences at any time. Again, any acute inflammation occurring in a confirmed gouty subject is the more serious on this account; and the same remark applies to injuries and shocks of all kinds, so that in such cases the prognosis is less favourable than it otherwise would be.

In the next place the future of a gouty patient has to be considered, as regards the prevention of subsequent attacks, or, indeed, the cure and eradicaton of the disease. It must always be recognised that gout is a recurrent affection and complete immunity can never be guaranteed, once the complaint has declared itself. At the same time undoubtedly not a few cases have occurred in which there has been but one attack, but this can only be expected under certain conditions. In giving an opinion on this point, the prognosis in any individual case will depend upon.—1. The degree of hereditary tendency to gout. 2 The age of the patient; for the earlier the period at which the disease begins, the less hopeful is the prospect of a cure. 3 The time the complaint has lasted from its commencement; and the frequency and duration of the gouty fits. If gout has become established, and especially if distinct chalk-stones have formed, it is quite impossible to eradicate it. 4. The habits, mode of living, and occupation of the patient. It is only when the patient is prepared to adhere strictly to proper rules of living that a cure can be hoped for. Those who in their occupation are liable to drink much, or who are exposed to cold or wet, are less likely to be cured. It may be remarked here that gouty subjects are less able than others to resist exposure.

Another point bearing upon prognosis refers to the duration of life in gouty persons. If the disease comes on late in life, and the paroxysms only occur at long intervals, while the organs are free from any organic mischief, gout may not appreciably shorten life, and the patients may even enjoy good health up to an extreme old age, provided they are sufficiently careful in their mode of living, and no accidental complications arise. Chronic gout unquestionably does tend to shorten the duration of life, to a greater or less degree in proportion to its severity, and more especially to the indications present that the kidneys, heart, or other important organs are organically diseased. This tendency is now recognised by most life-insurance companies.

It has been supposed that gout is a protection against certain other diseases, such as phthisis and diabetes, and therefore its presence has been in some instances regarded as a benefit, but how far there is any real foundation for this belief is a matter of considerable doubt.

TREATMENT.—It is important at the outset to lay stress upon the fact that, although there are certain well-defined principles applicable to the treatment of gout in its various phases, it is a great mistake to follow a regular routine method under all circumstances, and every case must be considered on its own merits, both as regards the patient himself and his surroundings. It

will be convenient to discuss this subject under certain general headings, promising that the administration of medicines is often the less important part of the treatment, and that the habits of life of the patient always need thorough supervision in all their details.

1 **Preventive and Curative Treatment.**—In a number of cases the primary object which should be aimed at is to prevent the development of gout; or to eradicate the tendency to subsequent attacks, if it has once declared itself, and to rid the system of the conditions which induce this complaint. These objects have especially to be kept in view in dealing with individuals who have a marked hereditary predisposition to gout; in cases where it has appeared at a comparatively early period of life, whether as a hereditary or acquired complaint, or where it is in an early stage, and in persons who, from their occupation, known habits, or the symptoms they present, are likely to become gouty. Moreover, even when confirmed gout has been established, preventive treatment may be carried out, with the view of diminishing the number of acute attacks, or even possibly of averting them altogether; and of obviating the implication of organs essential to the well-being of the economy. In order to carry out these objects in any particular case, the patient must intelligently recognise the fact that success in treatment mainly depends upon himself, and upon his willingness constantly to regulate his mode of living according to principles suitable to his condition, which need to be more or less strict in different instances. The general nature of the rules to be adopted will be evident from a consideration of what has been stated in discussing the etiology and pathology of gout, but they require to be briefly noticed here. The ends sought in carrying out these rules are to prevent an undue formation of urates in the system; to maintain the digestive and assimilative organs in a condition of healthy activity, and to promote the elimination of urates by the kidneys, especially if at any time there appears to be a tendency to their accumulation in the body.

(a) **Diet.**—Moderation in the quantity of food is the first point to be attended to in the treatment of the gouty diathesis. It is not necessary or desirable to restrict persons who are gouty to a very low diet, as is sometimes done, especially if they are in any way weak, but an amount sufficient for proper nourishment in each individual case must be consumed, and at no meal should the stomach be uncomfortably filled. The meals must be taken at regular times, and not hurriedly, so as to avoid boiling of the food. Very late dinners, as well as suppers, should be prohibited, but it suits many persons better to dine at six or half-past six o'clock than at mid-day. The nature of the food is highly important. It is quite unnecessary, and probably would be in most instances injurious, to restrict the patient to a vegetable diet, but a due proportion of animal and vegetable substances should be allowed. At the same time, in persons who have any tendency to gout, an essential part of the treatment often consists in diminishing the amount of meat which they consume, this being far in excess of what is needed, or can be got

rid of by the system without injuring it. Indeed, the aim must be to reduce all kinds of nitrogenized food, whether animal or vegetable, to such an amount as the system can satisfactorily dispose of, due regard being had to the proper nutrition and strength of the body, and thus to diminish the waste products resulting therefrom. As regards the kinds of animal food which are suitable for gouty subjects, white fish, chicken or fowl, game, and mutton are the best forms. Tender and underdone beef may be taken in moderation from time to time. Pork or veal, dried and salted meats, and rich dishes of all kinds, had better be avoided. Such vegetables should be partaken of as are known to be digestible, but those which contain much woody fibre, or which create flatulence, must not be indulged in. There is a notion that celery is beneficial in gouty cases, and the writer has recently met with an intelligent person, who has long been a martyr to gout, and he strenuously affirms that he has derived much benefit from taking celery freely, both in an uncooked form and stewed. Gouty subjects should either abstain altogether from, or only take a very limited quantity of, sugar and saccharine articles of diet. Hence, although digestible fruits may often be taken with advantage in moderation those which are very sweet must be used with particular caution. Stewed and baked fruits often agree well, but fruit-tarts, and, indeed, pastry of all kinds, should be interdicted. The juice of oranges or lemons is considered beneficial for gouty persons, and perhaps with good reason. It may be laid down as a rule to be invariably followed, that such persons should always limit themselves to simple meals, and not indulge in a number of courses; and that they should avoid everything which their experience tells them is, in their case, indigestible. It has been recommended that salt should be avoided by gouty subjects, so as not to add sodium to the system, for combination with uric acid.

(b) *Drink.*—The question of drink demands the most careful consideration and attention in every case in which gout is either threatened or has become established. It may be affirmed that no strict rules can be laid down, applicable to all cases, but there are certain broad principles which have to be borne in mind. An abundance of good and pure drinking-water is to be commended, but it should be taken mainly between meals. It is a good plan for the subjects of lithiasis to take a tumblerful of water before retiring to rest at night. Effereesing potash or lithia-water may be substituted for ordinary water with advantage, the dissolved salts forming soluble compounds with uric acid, but soda-water must be avoided. Tea and coffee may be taken in moderation, provided they do not disagree. With reference to alcoholic drinks, in a considerable number of instances one of the first objects in the treatment of the gouty diathesis should be the regulation of the use of this class of beverages. This indication is obvious enough when the condition is evidently due mainly to excessive indulgence in these beverages; but even when the patient is temperate, it may be that in his case the amount consumed needs to be reduced or total abstinence enforced,

especially if there should be a strong hereditary predisposition to gout, or if the complaint appears in early life. Some patients are undoubtedly better if they take no stimulants whatever; others, however, can take proper kinds in moderation with advantage. It may be laid down as a general rule that malt liquors and all stronger wines are injurious, and should be interdicted. Those which are most suitable are good claret, hock, moselle, chablis, or sauternes. Even these must, however, be only indulged in in strict moderation. A small quantity of good dry sherry suits some gouty patients very well. A little brandy, well-diluted, often agrees better than any other kind of alcoholic liquor; or in some cases whisky or gin may be substituted. Whatever stimulant is selected, it should only be taken at meal-times, and the habit of drinking between meals is strongly to be deprecated. Persons who are distinctly gouty should avoid any excess on every occasion, and even if they do not absolutely abstain, they may find it beneficial to do so from time to time, especially if there should be an abundant deposit of lithates in the urine, or if symptoms should occur which the patient recognises as being of a gouty nature. It is highly important that any alcoholic drink employed by gouty subjects should be sound and of good quality. There can be no doubt but that due attendance to the rules just sketched will prevent the development of gout where it is threatened, and will also check its progress, and avert the occurrence of acute attacks. The difficulty is to persuade patients to carry them out properly.

(c) *General hygiene.*—Inadequate exercise is a hygienic error which has frequently to be rectified in the treatment of the gouty state. Sedentary habits must be combated, whether due to the occupation or to indolence; and it must be insisted upon that a due amount of out-door exercise is taken daily, though violent exertion, tending to cause fatigue and exhaustion, must be avoided. Walking and horse-exercise are highly beneficial, especially in the case of those who live rather too freely. Even carriage-exercise is useful, so that the patient may have the benefit of the fresh air. General active habits should be encouraged, and any disposition to undue luxuriousness in the mode of living checked. The patient should retire to rest and get up early. Another point of importance, more particularly with reference to the vocation of the patient, whether professional or other, is that he should as much as possible avoid excessive mental labour, or any great strain upon the mental faculties, but especially worry and anxiety of all kinds. The writer has at present under observation a case in which the influence of these causes in bringing out eczema and other irregular symptoms of gout is strikingly illustrated. It is also important to pay attention to the cutaneous functions, and to protect the surface of the body from the injurious effects of cold. Warm clothing should be worn, in keeping with the weather, and those who can bear it may wear flannel next the skin. With regard to baths, many persons are decidedly the better for using a cold or tepid bath every morning, followed

by energetic friction; in other cases the employment of the warm bath at proper intervals, or even of the Turkish bath, answers best. It is certainly beneficial in some instances, either for those who are already afflicted, or those who are threatened with gout, to go through a course of treatment in a hydropathic establishment from time to time, under due medical supervision. Climate demands attention, whenever the circumstances of the patient allow a choice to be made. It may be advisable for gouty patients to reside permanently in some warm and equable climate, or at any rate during the winter and early spring. In this way attacks may often be warded off, and the disease thus prevented from making progress. Those who are obliged to remain in this climate during the inclement seasons should avoid exposure to wet and cold, as well as sudden changes of temperature, and night air. Their bedrooms should be warm and well-ventilated, and during cold weather it may be desirable to keep a small fire burning during the night. Heated and badly-ventilated rooms as well as crowded places of public resort, must be avoided.

(d) *Medicinal treatment*.—There can be no doubt but that the judicious use of certain medicines may assist materially in warding off or mitigating the gouty condition, and in preventing the occurrence of acute paroxysms. Those which are specially called for in cases of established chronic gout will be presently considered. In the meantime, it may be stated that the digestive functions require particular attention, and medicines which promote these functions are often of the greatest service, if they should be disordered, and especially if there should be a tendency to undue formation of acids in the stomach. A course of alkalies or acids according to the indications of each case, may prove most serviceable, combined with some simple bitter infusion or tincture. Certain alkalies and alkaline earths are also valuable on account of their power in promoting elimination of lithic acid, by forming soluble salts with this acid, which pass away in the urine, and some of them probably act beneficially in other ways. Those which are most useful for this purpose are salts of potash and lithia, but some practitioners prefer magnesia or lime. The best alkaline salts are the citrate or carbonate, or brands of lithia being the most soluble of all. Soda-salts should not be used, except when it is desired merely to influence the digestive functions. Either of the salts above-mentioned may be employed from time to time, and they must be taken well-diluted, and on an empty stomach. Magnesia or its carbonate may be given with advantage if there is much acidity, and if the bowels are habitually constipated. Saline aperients are often of great service, and they may be beneficially administered in small doses, freely diluted, and regularly repeated, when they also act on the other excreting organs. In many cases other aperients may be employed at intervals with advantage, but strong purgatives must only be used with much caution, and this especially applies to mercurial preparations, which, if taken too freely, may prove

highly injurious to patients who have any tendency to gout. The administration of cholagogues from time to time may be of considerable service. Medicines may be given to assist the action of the skin, if this should be defective, such as liquor ammoniac acetatis.

(e) *Mineral Waters and Baths*.—Certain mineral waters are of the greatest value in the treatment of the gouty diathesis, and they offer the advantage that patients will often use them, habitually or at intervals, when they will not undergo a course of regular medicinal treatment; while the water thus taken internally is itself of service. Many of these agents must, however, be employed only under proper medical supervision, otherwise they may do considerable harm. Space will not permit any lengthy discussion of this subject here, and it must suffice to mention that in different cases the kind of mineral water employed must be varied according to the object desired to be accomplished, and according to the indications presented by the patient, for what suits one may be highly injurious to another. These waters are employed both internally and in the form of baths, some of them belonging to the class of thermal waters. Those chiefly used in gouty conditions are the waters of Bath, Buxton, Harrogate, Leamington, and Cheltenham in this country, Strathpeffer and Moffat in Scotland; and Carlsbad, Vichy, Wiesbaden, Baden-Baden, Ems, Royat, Aix-la-Chapelle, Aix-les-Bains, Friedrichshall, Hunyadi János, Pullna, Seidlitz, Homburg, Kissingen, Wildbad, Ragatz, Gastein, Elster, Tarasp, Apollinaris, and similar waters from foreign countries. Some of these may be taken regularly or at intervals, for the purposes which they respectively fulfil, or if circumstances permit, a systematic course of treatment from time to time, at certain of the places mentioned, may be recommended. See MINERAL WATERS.

If we leaving the subject of the preventive treatment of gout it needs to be insisted upon that those who are particularly liable to this disease, whether from their occupation or any other cause, should pay special attention to preventive measures, and also that those in whom the disease has already manifested itself must take every precaution to avoid the known causes of acute attacks, for each attack tends to make matters worse.

2. *Treatment of Acute Gout*.—When a fit of acute articular gout sets in, it is on no account to be permitted to run its course unmodified by treatment, else serious mischief is liable to arise. At the same time it is requisite to refrain from adopting too active measures. Our objects should be to shorten the attack; to restore the affected parts to their normal condition; and to relieve symptoms. In the first place, attention must be paid to the diet. The aim should be to make this as low as is compatible with the condition of the patient, especially if the attack presents an acute and sthenic type. In young and strong patients the diet should at first consist of farinaceous substances, a little milk, and abundance of water, barley-water, or toast-and-water. Those who are advanced in years, weak, or broken-down in health, or who have long suffered from gout,

require a more nutritious diet; but it should be easily digestible, consisting of beef-tee and good soups, milk, eggs beaten up, and such articles, the quantities being regulated by the requirements of each case. As the symptoms subside, the food must be gradually improved, fish, fowl, and meat being allowed in succcession, but in strict moderation, and due care must be exercised subsequently. If possible, all kinds of alcoholic stimulants should be interdicted, but it may not be desirable to cut them off entirely in some cases, either on account of the previous habits or present condition of the patient, and then it is best to give a definite quantity of brandy or whisky, well-diluted, with the food. For those who cannot take spirits, the writer has found a little good hock or waterne answer well.

As regards medicinal agents, colchicum has long held the most prominent place in the treatment of acute gout, and is regarded almost as a specific. There can be no doubt as to the influence of this drug in relieving the inflammatory symptoms, and shortening the paroxysms of gout, although it is by no means settled how it acts. Its effects must be watched, however, for it does not agree in every case. It has been alleged that colchicum renders the patient more liable to subsequent attacks of gout, but for this notion there does not seem to be any real foundation. The tincture or wine of colchicum may be given in doses of ten to twenty or even twenty-five minims every four or six hours, and either of these may be combined with the citrate or carbonate of potash or lithia, these salts being also of great service in the treatment of acute gout. It is necessary to keep the bowels acting freely by means of suitable aperients, and saline purgatives are of considerable value for this purpose. Other aperients, such as compound rhubarb pill, cal-scyth, podophyllin, or even calomel or blue pill, may be employed in appropriate cases. Diuretics may be given freely, in order to promote the action of the kidneys; and if the cutaneous functions appear to be defective, some mild diaphoretic may be administered, or it may even be desirable to employ the hot-air or vapour-bath. Medicines may be needed for the relief of symptoms, especially pain and sleeplessness, for which Dover's powder or other preparations of opium, chloral, or bromide of potassium may be indicated. In very severe cases hypodermic injection of morphia is of much service.

Venesection ought never to be practised in the treatment of acute articular gout; for although immediate improvement may perhaps be thus produced, the ultimate results are highly unsatisfactory. Even the local removal of blood, by means of leeches applied near an affected joint, is dangerous, and had better be avoided, on account of the permanent local mischief which such a measure is liable to induce.

Local treatment.—The affected parts in acute gout should be kept entirely at rest, and placed in a comfortable position, supported by pillows, and either horizontal or elevated, according to the feelings of the patient. In ordinary cases it is sufficient to wrap up the joints in flannel, or to surround them with cotton-wool completely

covered with oil-silk or other impervious material, by which means a kind of local vapour-bath is kept up. If the pain is considerable, local applications must be used, of which the most useful are warm fomentations, to which tincture of opium or belladonna may be added, poppy fomentations, localised steaming, belladonna liniment, tincture of aconite, oleate of morphia, or a solution containing morphia and atropine. Those last-mentioned may be smeared or painted over the surface, or applied by means of lint covered with oil-silk. A blister in the neighbourhood of a gouty joint may be of service, if the attack be asthenic, and also if effusion or much stiffness remain. During recovery, benefit may be derived from careful friction with some stimulating liniment, shampooing, gentle passive movements, douching with salt and water, or the application of a light bandage or elastic support, should there be a tendency to permanent thickening and stiffness, or to oedema and enlargement of the veins.

The acute forms of *irregular gout* must be treated according to their nature, and here it must suffice to offer a few general remarks on the subject. If serious internal symptoms arise, which are distinctly of a gouty nature, and especially if they occur as retrocedent phenomena, it is important to try to excite inflammation in the joints, by means of local heat, friction, and sinapisms. Colchicum may be of service in the non-articular, as well as in the articular form of gout. In painful affections opium or other anodynes are called for; and frequently the administration of alcoholic and other stimulants is indicated, with anti-spasmodics, such as ammonia, ethers, camphor, musk, or belladonna, especially when the stomach or heart is affected. In conditions attended with signs of much depression or collapse, external heat may be applied over the body, or sinapisms to the limbs and over the cardiac region. In the treatment of inflammatory diseases associated with gout much care is required, especially in resorting to depletory measures. The existence of the diathesis must always be borne in mind.

3. Treatment of Chronic Gout.—When gout becomes an established chronic disease, the same general rules of treatment are to be observed as in the prevention or attempted cure of the complaint, but they often need modification in particular cases, according to the conditions present. Similar medicines are also indicated, and lithia is particularly valuable, and may even aid in removing gouty deposits; but others may be added to the list, which are suitable in different cases. Thus, colchicum is often of much service, taken habitually or from time to time, in the form of extract at night, or a few minims of tincture or wine two or three times a day, combined with other medicines. Among the many therapeutic agents employed in the treatment of chronic gout under different circumstances may be mentioned benzoic acid or benzoate of ammonia, phosphate of ammonia, phosphate of soda, iodide of potassium, bromide of potassium, carbonate of alumina, lime-juice, guaiacum, ammoniacum, and tonics, especially quinine, tincture or infusion of cinchona, or mild ferruginous

preparations. Undoubtedly most of these are of use in appropriate cases of chronic gout, to serve their special purposes. Symptoms connected with various organs frequently call for attention in this disease, and they must be treated by appropriate remedies. It may be remarked that if diarrhoea should set in in gouty cases, it should not be hastily arrested, as this may be a mode of relief to the system. With regard to the local conditions in chronic gout, it is affirmed that the prolonged use of some of the mineral waters previously mentioned, both internally and in the form of baths, such as those of Aix-la-Chapelle, Aix-les-Bains, and Baden-Baden, may succeed in removing to some extent deposits of urates, and in diminishing stiffness and thickening of joints. For these purposes local measures may also be of service in some instances, provided the morbid changes are not too far advanced, namely, occasional blistering or application of iodine, the prolonged use of wet bandages, friction with liniments, shampooing and passive movements; or systematic compression by means of some plaster. Solutions of alkalies or alkaline carbonates, and especially of carbonate of lithia, have been kept applied to gouty joints and other parts for a long time, under the belief that deposits of urates may be thus dissolved. In the writer's experience no such effect has ever been thus produced, although the constant application of moisture may be useful. Superficial accumulations of urates should not be interfered with unless they become troublesome, when it may be desirable to puncture the skin, and let the contents out. The propriety of removing large masses by operation may come up for consideration, but this should only be attempted if there is every probability that they can be entirely removed without any difficulty, and if the patient is in a fit state for the operation. When abscesses or ulcers form, they come under the treatment of the surgeon, but it may be observed that simple dressings usually answer best in these cases, and they may sometimes be advantageously dressed with solution of carbonate of potash or lithia. It must not be attempted to heal them up too rapidly, as the discharge may be a relief to the system, and it may even be necessary to enlarge the opening of an abscess. Under any treatment it is by no means an easy matter to induce gouty sores to heal.

The treatment of the various chronic organic diseases which are liable to arise in the course of gout must always be kept in mind, but the reader is referred to other appropriate articles for a consideration of this part of the subject.

FREDERICK T. ROBERTS.

GRAND MAL. (Fr.)—A term applied to epilepsy when it assumes the form of a severe convulsive attack. See EPILEPSY.

• **GRANULAR KIDNEY.**—A morbid condition of the kidney, in which this organ is the seat of fibroid change, and as a result becomes contracted, hard, and granular. See BRISTOL'S DISEASE.

GRANULAR LIVER.—A synonym for cirrhosis of the liver, in which the organ presents

a granular appearance, on its surface and on section. See LIVER, Diseases of.

GRANULATION (*granulum*, a little grain). In medical pathology, granulation is synonymous with tubercle in its isolated form, the individual tubercles being called 'gray' or 'yellow' granulations, according to their appearance. See TUBERCLE. In surgical pathology, the term granulations is applied to small vascular prominences, consisting of embryonic tissue, growing on the surface of wounds or ulcers, and by which the healing process is carried on—whence the expression 'healing by granulation.' When granulations assume the appearance of an exuberant growth they constitute what is called 'proud flesh' (see CICATRIZATION, and ULCER.)

GRANULIE (French).—A synonym for tuberculum. See TUBERCULUM.

GRAVEDO. (*gravis*, heavy).—A synonym for common catarrh, so applied on account of the sensation of weight in the head present in that affection. See CATARRH.

GRAVEL.—**DEFINITION.**—The deposit in, and excretion from the urinary passages of gritty particles with the urine.

ÆTIOLOGY.—The same causes which produce dyspepsia are frequently productive of lithic acid gravel, such as indolent habits, excess of food and drink—especially of nitrogenous and saccharine articles, and the too free indulgence in the use of fermented liquors. Epidemic causes connected with climate and the nature of the drinking water, hereditary predisposition, and many slight or serious organic diseases, may explain the appearance of gravel in those, and especially in women, who commit too dietetic excess, or who are total abstainers. See OXALIC ACID DIATHESIS, PHOSPHATIC DIATHESIS, and URIC ACID DIATHESIS.

VARIETIES.—Gravel may be composed of (1) lithic acid and its compounds, (2) oxalate of lime, (3) phosphate of lime, or (4) the triple phosphate of lime, magnesia, and ammonia. By far the most common form of gravel, and that which alone need now be considered, is the lithic acid. This, owing chiefly to its great insolubility, is frequently deposited in the kidney and bladder, and is seen in the newly-passed urine in the form of the well-known reddish-brown crystals, often described as resembling Cayenne pepper grains. The supernatant urine is generally clear, rather dark in colour, and of a distinctly acid reaction.

SYMPTOMS.—The passage of uric-acid crystals or gravel frequently causes no subjective symptoms, and is consistent with perfect health. Sometimes, however, it gives rise to, or is accompanied by, both general and local disturbance of function. The general symptoms are those of dyspepsia, namely, flatulence and heartburn after meals, eructations, headache, muscular cramp, depression of spirits, and a sense of malaise. Locally, there is dull aching in the lumbar region, not increased by movement; frequent micturition; a sense of heat and irritation at the neck of the bladder and along the urethra, especially during and after voiding water; and sometimes the appearance

of a faint cloud of mucus or a slight tinge of blood in the urine.

TREATMENT.—From what has been said, it follows that the most important points in the treatment of gravel are strict limitation as to the quantity of food; the avoidance of highly-seasoned, very rich, or sweet dishes; the preference for vegetable rather than for animal food; abundant exercise in country air; and the absence or very sparing use of alcoholic liquors. Medicinally there may be given diuretics, to increase the quantity of the urine and facilitate the escape of gravel; pure water, alkalis, and alkaline waters freely diluted, to act as solvents of uric acid; and saline aperients and saline waters, to promote digestion and assist in ensuring the free action of the liver and alimentary canal.

W. CADGE.

GRAVES' DISEASE.—A synonym for exophthalmic goitre, to which the late Dr Graves of Dublin called special attention. See EXOPHTHALMIC GOITRE.

GREEN-SICKNESS.—A popular synonym for chlorosis, applied on account of the greenish colour of the skin sometimes present in that disease. See CHLOROSIS.

GRIPPE (Fr)—A French synonym for influenza. See INFLUENZA.

GROWTH, Disorders of.—See ATROPHY, HYPERTROPHY, and MALFORMATIONS.

GRUTUM.—A term applied to small, hard, white globules developed from the epidermis, and commonly met with on the face, especially on the eyelids, cheeks, and temples. They are called grutum, from bearing some resemblance to oatmeal *gruts*, and have likewise been named *milium*, as comparing them in size and roundness of figure to millet-seeds. Other of their synonyms are *miliary tubercles* and *pearly tubercles*.

ERASMUS WILSON.

GUINEA-WORM.—SYNON.: Dracunculus, *Filaria medinensis*. Supposed by some persons to be the 'fiery serpent' of Mosiac history.

DESCRIPTION.—The Guinea-worm is a nematoid parasite, usually measuring from one to three feet in length, and having a breadth of about one-tenth of an inch. Examples have been described as reaching six feet in length. In the adult condition it infests the feet and legs, as well as other parts of the body that are much exposed. The female only is known, but its more or less finely pointed and subulate tail has often caused it to be described as the male parasite (by Owen and others). The anatomy of the worm has been described by Busk, Carter, and Leuckart, and more particularly by Bastian, who has also thrown much light upon the structure and development of the embryos as they are found within the body of the parent worm (*Lanc. Trans* 1863, p. 101 et seq.). The discovery of the viviparous mode of reproduction of the dracunculus is probably due to Jacobson, whose observations were subsequently verified by Owen, Busk, Bastian, the writer, and also by Robin, Carter, Davaine, and Moquin-Tandon. As regards the development of the worm outside the body of the parent, the only observations of importance are those of the Russian

traveller, Fedtschenko. According to the deceased (as verbally communicated to the writer during his visit to England), the escaped embryos of the Guinea-worm perforate the skin of minute aquatic crustaceans (Cyclops). Here, after a period of only twelve hours, the embryos undergo a first change of skin, parting with their long fine tails, which eventually become comparatively blunt and forked. At the expiration of one month and six days they acquire their highest larval stage of growth within the Cyclops, traces of the reproductive organs being already seen, and thus, along with the intermediate hosts, as young males and females, they are transferred to the human stomach. Fedtschenko expressed his belief that it was either in the stomach or in the intestine that they subsequently copulated, producing a progeny after the manner of Trichina; the males perishing and passing away per anum, whilst the females migrated through the tissues towards the surface of the body. Whether or not this view be correct, Fedtschenko's discovery of the fact that the dracunculus needs to pass through the body of an intermediary bearer loses none of its practical and scientific interest. In Dr Bastian's opinion the young dracunculi are the product of a non-sexual process. It should not be forgotten that Dr Carter, who is a great authority on all matters connected with the natural history of the guinea-worm, has stated that in a school of fifty boys bathing in a pond, the sediment of which swarmed with microscopic tank-worms (*Urobates palustris*), no less than twenty-one were attacked with dracunculus during the year; whilst the boys of other schools, bathing elsewhere on the island of Ibmday, were, with one or two individual exceptions, not affected. Facts of this kind long led the writer and others to suppose that sexual maturity was attained prior to the entrance of the worms into the human bearer. Thus, the writer has stated it to be probable (*Entozoa*, 1864, p. 388) that 'the sexes associate in muddy waters during the monsoon, after which act the males perish, whilst the females are left to find their opportunity for a mode of direct entrance into and further development within the human body.' It is clear that some waters are more infested by young guinea-worms than others. It is also tolerably certain that human infection is due to the passive immigration of the parasites. We fear, however, that the notion of ingress in a direct manner through the ducts of the skin must now be abandoned. Its former acceptance appeared to be in entire harmony with the data supplied by Indian army surgeons and other observers.

The geographical distribution of the guinea-worm is limited to inter-tropical climates, being, for the most part, confined to certain districts of Asia and Africa. It occurs also in the island of Curaçoa and in Brazil. [On this subject see Dr J. F. da Silva Lima's Memoir in *Thet. clemmarum* for February, 1879.] It is endemic in its action; all races of mankind, without reference to age or sex, being liable to be attacked in the guinea-worm districts.

TREATMENT.—Clinically speaking, the mode of treatment pursued at the present day does not differ materially from the old method adopted by the Persian surgeons, who extracted the worms

by gentle and continuous traction, winding the exposed end of the worm round a small stick of ivory, bone, or wood. If the parasite be ruptured, local and even severe constitutional mischief is apt to ensue. See DRACUNCULUS.

T. S. CONNOLD.

GUMMA (Lat., gum).—A growth occurring in syphilis so named on account of its supposed superficial resemblance to gum. See SYPHILIS.

GUMS, Diseases of.—See MOUTH, Diseases of.

GURGLING—A physical sign heard on auscultation of the chest or abdomen in certain conditions, due to the movement of gas and fluid within a cavity, whether normal or abnormal.

A gurgling sensation may also be felt at times in the intestines, as over the cæcum in typhoid fever. See PHYSICAL EXAMINATION.

GUTTA ROSACEA (*gutta*, a drop; *rosea*, rosy).—A synonym for *Acne rosacea*. See ACNE.

GYMNASTICS (*gymnás*, naked). See EXERCISE.

GYNÆCOLOGY (*gynē*, a woman, and *logos*, a word).—This term in its literal sense means a doctrine or discourse concerning women. In medical language, it comprehends the study of the diseases peculiar to women. See WOMEN, Diseases peculiar to.

H

HABIT OF BODY.—This expression signifies the sum of the physical qualities of an individual, and is sometimes used synonymously with *constitution*. Thus we speak of a *full* habit, a *sparse* habit, and an *apoplectic* habit.

HABITS. See DISEASE, Causes of, and PERSONAL HEALTH.

HÆMACYTOMETER (*haima*, blood, *metron*, a cell, and *metron*, a measure).—Definition.—An instrument by the aid of which the number of corpuscles contained in a given volume of blood can be ascertained.

DESCRIPTION.—All methods employed for this object consist in making a definite dilution of a certain quantity of blood, and counting the number of blood-corpuscles in a certain volume of this dilution. Vierordt, who originated the method, drew uniform lines of diluted blood upon a slide, and, after it was dry, counted the corpuscles in a certain length of line. Cramer substituted for these lines what may be termed a capillary cell, and Potain and Malassez employed a capillary tube, and a microscope provided with an eyepiece ruled in squares. Hayem substituted for the tube a cell, the depth of which gave one dimension of the volume of dilution, while the lines upon the eyepiece furnished the others. The writer's instrument is an adaptation of Hayem's, with certain modifications; the diluting apparatus is similar, but of different capacity, and the lateral dimensions of the volume of dilution are obtained, not by a microscope-eyepiece, but by lines engraved upon the glass slide at the bottom of the cell. The instrument can thus be used with any microscope, an important convenience in practical use. The alteration in the capacity of the diluting measures facilitates the counting, and provides a much simpler mode of statement of the result. The apparatus, which is made by Hawksley, consists of (1) a pipette graduated to 995 cubic

millimeters for measuring the diluting solution; (2) a capillary tube for measuring the blood, containing five cubic mm; (3) a small glass jar, and a stirrer for making the dilution; and (4) the cell for counting, .2 mm deep, and ruled at the bottom in squares, each .1 mm. in length and breadth. The slide bearing the cell is fixed on a small metal plate, to which two springs are attached; these keep the cover-glass in position when applied.

Various solutions have been employed for making the dilution. That which the writer has found to answer best, as differentiating most clearly the red and white corpuscles, consists of sulphate of soda, 104 grains; acetic acid, 1 drachm; distilled water, 6 ounces.

In using the hæmacytometer, a drop of the dilution is placed in the centre of the cell; the cover-glass and springs are applied; and in a few minutes the corpuscles have sunk to the bottom of the cell, and are seen lying within the squares. The dilution of 5 cmm of blood in 995 cmm. of solution is 1 in 200; each square contains the corpuscles from a volume of dilution .2 mm. in one, and .1 mm. in each of the other dimensions—that is, 2 cubic .1 mm., or the .002 part of a cubic mm. But the dilution being 1 in 200 this volume of dilution contains just .0001 cm. of blood. The number of corpuscles in a square, multiplied by 100,000, is thus the number in a cubic millimeter of blood—the common mode of statement. In order to limit error, the number of corpuscles in ten squares should be counted, and this number multiplied by 10,000 is the number per cubic millimeter. The average number in health is about 5,000,000. Blood of normal richness, then, contains about 50 corpuscles per hæmacytometer square. Therefore the number in two squares of the instrument will always represent the proportion of the corpuscular richness to normal blood (= 100)—that is, the percentage proportion to normal. It is, there-

first, convenient to take the volume of blood represented by the two squares ('000012 cubic millimeter) as the standard volume, or 'hæmic unit.' For instance, it is found that the blood diluted presents in ten squares 375 corpuscles or 75 in two squares ('hæmic unit')—that is, 75 per cent compared with the normal. To learn the number per cubic millimeter we have only to multiply 375 by 13,000, = 3,750,000. In counting the white corpuscles, if they are not in considerable excess, it is most convenient first to ascertain the number of red corpuscles per square, and note how many squares are contained in a field of the microscope. If then the focus is raised so that the corpuscles are becoming indistinct, the white ones, from their higher refracting power, will appear like bright points, and the number in a series of fields can easily be counted. For example, the number of red corpuscles per square has been found to be 40, and the field contains 15 squares, that is, 600 corpuscles per field. Ten fields contain 15 white corpuscles, the proportion of white to red will, therefore, be $1 \text{ to } \frac{600 \times 10}{15} = 1 \text{ to } 400$.

With this apparatus we may readily ascertain, within a small limit of unavoidable error, the corpuscular richness of the blood, an important element in many morbid states, such as anemia; and we can thus ascertain the indications for, and observe the effect of, therapeutic agents. It is, however, very desirable in these cases to ascertain also the richness of the corpuscles in hæmoglobin (see HÆMOGLOBINOMETER). The instrument may also be employed for ascertaining the globular richness of milk or other liquids. W. R. GOWANS

HÆMATEMESIS (*ajpa*, blood, and *êma* I vomit).—SYNON.: *Pr. Hématémie*, Ger *Blutbrechen*.

DEFINITION.—Vomiting of blood, dependent on a variety of morbid conditions.

ÆTIOLOGY AND PATHOLOGY.—Hæmorrhage into the stomach may arise—1. From the laceration of an artery. 2. From venous or capillary congestion of the mucous membrane. 3. From causes affecting the blood itself, so that it tends to transude through the vessels under pressure of the circulation.

1. The most frequent cause of hæmatemesis is an ulcer of the stomach. It occurs, according to the late Dr. Brinton, in about one-third of all the cases of gastric ulcer that come under treatment. The bleeding usually takes place shortly after a meal, and the quantity rejected varies greatly. In some cases, it is so small that it may require careful examination to discover it; whilst in others enormous quantities are vomited, and often also passed through the bowels. The splenic artery is most frequently the source of the bleeding, but it may arise from the coronary, the superior pyloric, or, more rarely, from the blood-vessels of some of the neighbouring organs, such as the pancreas, liver, or spleen, to which the stomach has become attached, and which may happen to form the base of the ulcer. It is not necessary that the ulcer should be of large size to produce hæmorrhage. Although it is most apt to occur in chronic

cases, instances have been recorded in which a large vessel had been laid open by an ulcer so small as to require careful search for its detection. It must be borne in mind that extensive bleedings may take place without any vomiting, and the source of the fatal illness be overlooked. Such cases are not of infrequent occurrence, and warn the practitioner that he should be on the alert, whenever signs of hæmorrhage present themselves, and that he should not rely too much on the absence of pain and vomiting. In cancer of the stomach profuse hæmorrhage is less common than in simple ulcer, the larger vessels being probably compressed by the new growth, which ordinarily commences in the submucous tissue immediately above them. But a constant oozing of blood is, on the contrary, more common than in simple ulceration. This blood, acted on by the gastric juice, constitutes the 'coffee ground' vomiting of the older authors. Its occurrence need to be looked upon as pathognomonic of malignant disease, but it is now known that its presence only shows that the bleeding has taken place slowly and in small quantities at a time. Occasionally profuse hæmorrhage takes place from the rupture of an aneurism into the stomach, and in a case which came under the writer's notice at the London Hospital, fatal vomiting of blood resulted from the perforation of the aorta by a fish-bone that had become impacted in the œsophagus.

2. Congestion of the portal system is a very frequent cause of hæmatemesis. The most marked and fatal cases of this kind occur along with plugging of the vena portæ or its large branches with blood-clots or cancerous matter. Such cases are very rare and vomiting of blood, arising from venous congestion, ordinarily results from cirrhosis, chronic congestion, and other diseases of the liver, in which the portal circulation is obstructed. More rarely the like occurrence is observed in persons suffering from diseased heart, especially where there is narrowing of the mitral orifice. In such cases, there is generally a co-existence of chronic catarrhal gastritis, and in all probability the bleeding takes place from the hæmorrhagic erosions so common in that condition. In one form of this disease enormous quantities of mucus are discharged. Sometimes there is considerable bleeding in these cases, but they are distinguishable from ulcer by the absence of pain, by the vomiting being only occasional, and also by the fact that the blood-stained vomit generally follows a profuse evacuation of colourless mucus, and is always of a dark colour. In females thus affected the catamenial discharge is generally profuse; and the attacks of vomiting do not necessarily coincide with the menstrual periods. It has always been held that hæmatemesis may replace the menstrual discharge. Without denying this, the writer has never met with a well-marked case of the kind. Hæmatemesis due to acute congestion is also a constant result of irritant poisoning.

3. Hæmatemesis also arises from causes affecting the blood, and predisposing it to ooze through the walls of the veins or capillaries. It occurs in this way in purpura, yellow fever, and in some cases of typhus. In jaundice, where bleeding

from the gums and other mucous membranes is so often observed, life may be suddenly destroyed by hæmatemesis. Occasionally a hæmorrhagic tendency manifests itself suddenly, without apparent cause, as in a case observed by the writer, in which a woman, about fifty years of age, was affected with severe bleeding from the nose, followed by excessive menstrual discharge, on the cessation of which profuse hæmorrhæmia took place from which she sunk. She had no jaundice nor other apparent cause for her illness, and after death the most careful scrutiny failed to detect disease in any organ. To this class of causes we should probably refer the hæmatemesis occurring in acute atrophy of the liver, and in pyæmia, as, in all probability, the oozing of blood through the vessels arises from changes effected in its chemical or physical composition.

SYMPTOMS.—Generally the patient in hæmatemesis is suddenly attacked with faintness, accompanied by a feeling of weight at the pit of the stomach, the countenance is pale, the pulse feeble and compressible, and in some cases actual syncope occurs. This state terminates by vomiting, and a greater or less quantity of blood is rejected from the stomach. When a large blood-vessel has been laid open, and the bleeding has taken place rapidly, the blood may be florid, but generally the hæmorrhage goes on so slowly that time is given for the action of the gastric juice upon it, and consequently it is of a dark colour. It is not often that the stomach is completely emptied, or perhaps the bleeding persists in small quantities after the vomiting has ceased, so that the stools are generally of a dark or pitchy character, from the admixture of blood that has passed into the intestines. The hæmorrhage may cease soon after the stomach has been emptied, or the vomiting of blood may recur from time to time, or—and this is very apt to occur in gastric ulcer—months or years may elapse before it again takes place.

DIAGNOSIS.—In some cases, when the blood has been slowly effused into the stomach, there may be difficulty in determining whether the dark colour arises from bile or blood. The microscope or spectroscope will be enough to settle this point, or the liquid may be boiled with alcohol, and tested for the biliary salts. It is not always easy to ascertain whether the blood has come from the lungs or from the stomach, as the patient is sometimes so much alarmed that he cannot say whether it was brought up by coughing or vomiting. As a general rule, the blood from the lungs is florid, mixed with mucus, alkaline, and frothy; that from the stomach of darker colour, intermixed with particles of food, and in masses. Again, hæmoptysis is generally preceded by symptoms referable to heart or lungs, such as cough, expectoration, and dyspnoea, hæmatemesis by the symptoms indicative of gastric or hepatic disease, such as those described above.

PROGNOSIS.—As a general rule this is favourable in hæmatemesis, more especially in first attacks. Dr. Beenton calculated that death resulted from this cause in only 3 to 5 per cent. of the cases of gastric ulcer; and it is still less frequently fatal where it proceeds from hepatic

congestion or cirrhosis. Still, the possibility of the bleeding arising from flooding of the portal vein, from the opening of a large artery, or from the bursting of an aneurism, should be kept in view, and the patient carefully watched.

TREATMENT.—When a large quantity of blood has been ejected from the stomach, the treatment must be prompt and decided. The patient should be maintained in a recumbent posture, and kept perfectly quiet. All food must be forbidden, and pieces of ice placed in the mouth to suck. If faintness be present, it is better not to give brandy, which almost always brings on vomiting, but to apply ammonia to the nostrils; or, if necessary, an emema containing brandy may be given.

The best styptics are gallic acid, alum, and acetate of lead. The gallic acid may be given in 10-grain doses, along with 10 or 15 minims of dilute sulphuric acid, and should be repeated frequently. Alum may be prescribed in infusion of roses, and the acetate of lead in 2-grain doses in the shape of a pill, or combined with acetic acid. Oil of turpentine is also used. Where the bleeding is slight, and there is good reason to believe it arises from portal congestion, the best treatment is to give a small dose of calomel, followed by sulphate of magnesia and dilute sulphuric acid in infusion of roses every three or four hours, until purging is produced.

For some days after severe hæmatemesis, the strictest quiet should be maintained; and, in the case of ulcer of the stomach, opium should be used, and the diet most carefully regulated; if rendered necessary by persistent bleeding, nutritive enemata should be substituted for food by the mouth, and all purgatives avoided. When the hæmorrhage has arisen from portal congestion, a free action on the intestinal canal should be commenced in a few days after the cessation of the hæmorrhage, so as to diminish the amount of blood in the venous system of the alimentary organs. S. FARWICK.

HÆMATHIDROSIS (*αἷμα, blood, and ἵδρως, sweat*).—Bloody sweat. See PNEUMATION, Disorders of.

HÆMATHORAX. See HÆMATO-THORAX.

HÆMATIN.—See HÆMOGLOBIN.

HÆMATINURIA, PAROXYSMAL (*hæmatin; and οὖρον, the urine*).—**SYNCH:** Hæmoglobinuria.

DEFINITION.—A paroxysmal affection of the system, manifesting itself by changes in the urine, caused sometimes by malarin, and sometimes by other conditions not yet determined; consisting in no anatomical change as yet recognised, and characterised by the occasional recurrence of constitutional disturbance, with discharge of dark, blood-stained urine.

ÆTIOLOGY.—The most important extrinsic cause of the tendency to this disease is malarious poison, the most important cause of the paroxysm is exposure to cold or wet; but the tendency may exist without malarial poison, and the attack may occur apart from any special exposure. Amongst intrinsic causes, sex is evidently important, for the disease is almost confined to males. It may occur in children, and may occasionally recur during a period of years.

ANATOMICAL CHARACTER.—The disease not being fatal, there is no evidence as to the existence of any anatomical change in the kidneys.

SYMPTOMS.—Hæmatinuria is paroxysmal, but not distinctly periodic. It may commence in childhood or during adult life. The attacks may occur once, twice, or thrice a day, on alternate days, once a week, or quite irregularly. The paroxysm may commence abruptly without any premonitory symptom, but is more commonly ushered in by a feeling of uneasiness in the loins and limbs, by shivering, and general chilliness. Sometimes it is preceded by slight jaundice, furred tongue, and other symptoms of gastric catarrh, and sometimes albuminuria precedes by a few hours or a day the occurrence of hæmatinuria. The more abrupt attacks frequently terminate by the discharge of the peculiar urine, and the next urine is normal, or nearly so. In some cases albuminuria lingers for a time after the discoloration has passed off. The characters of the urine are very peculiar. Its colour is like port or like muddy port wine; its specific gravity ranges from 1015 to 1035; it is acid, or faintly alkaline, highly albuminous; sometimes it contains excess of urea; and throws down a copious sediment. This contains very few or no blood-corpuscles, but an immense amount of granular blood-pigment, with numerous tube-casts—hyaline or epithelial, often loaded or coated with amorphous granular matter, and with minute crystals of oxalate of lime. The colour is not due to blood-corpuscles, and it is said not to be due to hæmatin, but to hæmoglobin. In some cases the urine is less affected, being merely albuminous, and not depositing pigment. It may be doubted whether this condition should be admitted to the same category as the disease under discussion, but cases which have come under the writer's observation seem to show that it is entitled so to rank.

DIAGNOSIS.—The only diseases with which intermittent hæmatinuria is likely to be confounded are hæmaturia, and renal calculus or gravel. From the former it is distinguished by the abundance of the blood-pigment, and the extreme rarity of blood-corpuscles, from the latter by the short duration of the attacks, the presence of the characteristic deposit, with the fact that the pains affect both loins, not merely one. It is sometimes important to distinguish the milder form, in which merely albuminuria occurs, from congestion or from commencing inflammatory Bright's disease. It is not always possible to distinguish these during the early hours of the attack, but the amount of general disturbance, the state of the tongue, the slight jaundice, the suddenness of the onset, and the absence of dropsy, generally suffice to make it clear.

PROGNOSIS.—The prognosis is good in paroxysmal hæmatinuria, as to the individual paroxysm. The tendency to the disease is also not unfrequently got rid of. It has not proved fatal in any case. But it appears sometimes to usher in, or to constitute, an early symptom of Bright's disease—the cirrhotic form.

TREATMENT.—As the paroxysm is spontaneously recovered from, little need be done, excepting with the view of alleviating the discomfort of the patient. He should go to bed and be kept warm, and have abundance of warm drinks.

In respect of diminishing or removing the tendency to the malady, various remedies have been found useful, among which may be mentioned quinine, tincture of cinchona, iron, arsenic, and chlorids of ammonium.

T. GRAINGER STEWART.

HÆMATOBIUM (αἷμα, the blood, and βίωσις, life)—A synonym for hæmatozoa. See HÆMATOZOA.

HÆMATOCELE (αἷμα, blood, and κήλη, a tumour).—**SYNON.**: Fr. *Hématocèle*; Ger. *Blutgeschwulst*.—**DEFINITION.**—The swelling occasioned by effusion of blood in the sac of the tunica vaginalis, or in a cyst connected with the testicle.

ÆTIOLOGY AND SYMPTOMS.—The extravasation of blood in hæmatocele may take place in a healthy state of the parts, or it may succeed or be combined with hydrocele. In both cases it may be occasioned by a blow, or by violent efforts made in straining especially in old persons, or when the blood-vessels are diseased. It may happen also from the accidental wound of a vessel in tapping a hydrocele. The blood effused, if small in quantity, mixes with the fluid of the hydrocele, occasioning slight enlargement without disturbance. If it be large in quantity, coagula are formed, inflammation is excited in the tunica vaginalis, and plastic exudation occurs on its inner surface, sometimes forming layers, and rendering the sac extremely dense and firm.

The testicle preserves the same relation to the remainder of the tumour as in hydrocele, being situated at its posterior part. Its position, however, is liable to similar alterations as occur in hydrocele, which are very difficult of detection, owing to the great thickening of the parts.

DIAGNOSIS.—A hæmatocele may be distinguished from a hydrocele by the absence of transparency, the obscure character of the fluctuation; the heavy feel of the tumour when balanced in the hand; and the sudden and accidental mode of its occurrence. In old chronic cases, in which the tunica vaginalis and its envelopes have become much thickened and indurated, the tumour possesses so firm a character, and feels so heavy and solid, that it is very liable to be mistaken for a chronic enlargement of the testicle; and the diagnosis, at all times difficult, in some instances cannot be satisfactorily made out by the most experienced hands. The records of surgery furnish many cases in which castration has been performed owing to a mistaken diagnosis. When doubt exists, it should be removed by the introduction of a trochar or by an incision before any serious operation, such as castration, is undertaken.

TREATMENT.—When hæmatocele succeeds a hydrocele, the blood, if small in quantity, mixes with the fluid of the hydrocele without producing irritation. The tinged fluid may be removed by tapping, and the operation can be repeated afterwards at intervals until the fluid is free from discoloration. Even when inflammation arises, if the sac be tapped and tension removed, and the patient be kept at rest, with ice applied to the part, the inflammation may subside. When, however, the blood effused is large in quantity, and when the inflammation is acute and threatens suppuration, the tumour should be punctured at

its upper part, a director introduced, and the sac freely laid open by incision. This must be done with care, so as to avoid wounding the testicle. A chronic hæmatocele with a very thickened sac must be cut into in the same way; and lateral portions of the sac may be excised, so as to lessen the wound for healing. The practitioner must bear in mind that the testicle is sometimes situated in front, as in cases of inversion, and is then very liable to injury in the operation of incision, and even in tapping.

Encysted hæmatocele.—Encysted hæmatocele implies an effusion of blood in the sac of an encysted hydrocele; and the treatment is the same as that required for ordinary hæmatocele.

Hæmatocele of the Cord.—Blood may also be effused in the areolar tissue of the spermatic cord, constituting *effused* hæmatocele of the cord, or in a cyst in the cord, constituting *encysted* hæmatocele of the cord. Such cases are very rare. T. B. COCHRAN.

HÆMATOIDIN.—See HÆMOGLOBIN.

HÆMATOMA (*αἷματωμα*, I fill with blood).—A peculiar form of bloody tumour, or a collection of extravasated blood that has undergone certain changes. It is observed more especially in connection with the ear, the scalp, and the meninges. See CEREBRAL HÆMATOMA, HÆMATOMA AURIS, MENINGES, CYSTIC, HÆMATOMA OF, and TUMORS. The term is sometimes also applied to fungus hæmatodes.

HÆMATOMA AURIS (*αἷματωμα*, I fill with blood, *auris*, of the ear).—SYNON.: The human ear; Fr. *Otématome*; *Hématome de l'oreille des aliénés*; Ger. *Othamatoma*, *Ohrblut gewulst von Geisteskranken*.

Definition.—An affection of the auricle, which occurs almost, if not quite exclusively, in the insane, and consists in the effusion of blood or bloody serum between the cartilage and its perichondrium, to such an extent as to form a distinct tumour.

Ætiology.—In most of the few cases of hæmatoma auris which have been published to show that this disease may occur in the sane, the description given of the patients rather points to their insanity than otherwise. It is most common in cases of general paralysis and mania (acute and chronic), but also occurs in melancholia, dementia, and idiocy. It is about four times as frequent in men as in women, and more often affects the left ear than the right. Sometimes both ears are affected, but seldom at the same time. There would seem to be, in many or all of the insane, a morbid condition of the vessels or other tissues of the auricle, which predisposes to the occurrence of hæmatoma. If this condition be present to a sufficient degree, the disease may arise spontaneously, in other cases a very slight injury may be sufficient to cause it; whilst in others very considerable violence is necessary for its production.

SYMPTOMS AND COURSE.—The disease first makes itself evident by the appearance of a swelling of about the size of a horse-bean; this is almost always upon the anterior surface* of the pinna, and usually in the neighbourhood of the fossa of the antihelix. The skin over the tumour is generally of a reddish or bluish-

red colour, but may be unaltered at first; the temperature of the ear is sensibly raised; the swelling is very painful and tender; there is no extravasation of blood from the cutaneous vessels; and the tumour is not odematous. At this stage, the effusion which has taken place between the cartilage and its perichondrium consists of dark red fluid blood. In rare cases the swelling does not increase further; the inflammatory symptoms subside after about a week; absorption gradually takes place; and only a slight thickening remains. More usually the tumour increases and may attain the size of a hen's egg, it becomes tense, elastic, distinctly fluctuating, and hot; and is often of a bright red colour. Its prominent anterior wall, consisting of skin, cellular tissue, and perichondrium, is felt to be thinner and less resisting than the posterior, which contains the ear-cartilage. In certain cases, however, owing to the brittle cartilage having split up, and portions of it having adhered to either wall, both walls present irregularly alternating characters. The time which a hæmatoma takes to attain its largest size varies from a week to a month; it then generally involves the whole of the concha, occluding the external auditory meatus; the folds of the auricle are lost, with the exception of the helix (which appears as a band running round the tumour), and the dependent lobule. The weight of the tumour causes the whole ear to fall somewhat forwards and outwards. Sometimes, especially in the presence of constant or repeated irritation, the inflammatory stage may last many weeks, and the deformity which always results from the affection is thereby greatly increased. Unless subjected to violence, it very rarely happens that the tumour opens spontaneously, although its tense and inflamed appearance often seems to indicate that such an occurrence is imminent. If rupture does take place, suppuration ensues; portions of cartilage come away, the cavity closes very slowly; and great deformity results. The most common course is for the inflammatory symptoms gradually to subside. The anterior wall becomes firmer, owing to a new deposit of cartilage upon its inner surface; the sense of fluctuation is gradually lost; and the tumour slowly diminishes in size, often yielding a somewhat doughy sensation to the touch. Occasionally, at this stage, some gaseous contents have been observed in the cavity. The colour of the skin over the tumour becomes gradually more dusky; it then passes into yellow and, later on, into an unnatural pallor. As the fluid contents become absorbed, the tumour becomes harder and smaller; folds again appear in the auricle, but do not correspond to the original ones; and the pinna remains permanently thickened, puckered, and often nodular.

ANATOMICAL CHARACTERS.—Many of these have been given above in explanation of symptoms, and do not require to be repeated. A shrivelled auricle, which has previously been affected by hæmatoma, presents, on section, two distinct layers of cartilage; these are of varying thickness, and separated from each other by vascular fibrous tissue, which often contains within it other small isolated plates of cartilage, and sometimes also small portions of bone. The fibrous tissue is the organised product of the original

ossifies; the two layers of cartilage have been developed upon the inner surface of the perichondrium; the loose portions of cartilage and lamæ which are occasionally seen, are developed from the fibrous tissue. It used to be supposed that the bone (which is soft, vascular, and contains well-developed Haversian systems) resulted from ossification of the ear-cartilage; but the writer has shown elsewhere (*Brit. Med. Journal*, Oct. 1873) that this is not the case.

PROGNOSIS.—The local affection is in no way dangerous, but it always leaves behind it a permanent characteristic deformity of the auricle. The sense of hearing is only affected by the occlusion of the auditory meatus; but this condition very rarely persists after the acute stage. The occurrence of hæmatoma auris affects the prognosis of the mental disease unfavourably, but does not necessarily indicate the approach of a fatal termination to the case.

TREATMENT.—Protection of the part from injury is usually all that is necessary. Cooling applications might be useful if inflammation were excessive. The tumour should not be opened, nor should a portion of the anterior wall be removed, as has been recommended; these procedures only lead to suppuration. It is useless to empty the cavity by aspiration, as it fills again with great rapidity. The treatment by pressure is very painful, and yields no good result.

CHAS. W. W. CORROLD.

HÆMATO-PERICARDIUM (*αἷμα*, blood; *περὶ*, about, and *καρδία*, the heart).—An extravasation of blood into the sac of the pericardium. See **PERICARDIUM**, DISEASES OF.

HÆMATO THORAX (*αἷμα*, blood, and *θώραξ*, the chest).—An extravasation of blood into the pleural cavity. See **PLEURA**, DISEASES OF.

HÆMATOZOA (*αἷμα*, blood, and *ζῷον*, an animal).—This term is of general application to all kinds of animal parasites dwelling in the blood and blood-vessels, but its employment is often restricted to certain of the nematoid entozoa, which display this habit in a more marked degree than the other parasites are wont to do. All classes of helminths are liable, at some time or other in the course of their lifetime, to take up their residence in the blood, but in the case of the *Tenias*, or rather of their *prosochætes*, this period is of very short duration. One or two species only of fluke-worms or trematodes play a similar rôle in man, the most important being the *Bilharzia*, which gives rise to an endemic hæmaturia at the Cape, and elsewhere in Africa (see **BILHAZIA**). Our knowledge of the nematoid hæmatosom dates at least as far back as the time of Knyssch (1665) who was acquainted with the strongvix which produces aneurism in the horse and other animals; whilst more than half a century later the subject received additions from the writings of Schulze (1735) and Chabert (1783); and subsequently from the memoir by Rayer (1845). About the latter period also the observations by Grube and Delefosse 'on a verminiferous condition of the blood of dogs, caused by a great number of hæmatosom of the genus *Filaria*,' excited much attention; but until quite recently it was not so much as suspected

that similar microscopic filarie infested the human body. In 1872 Dr. Lewis announced the important discovery of the existence of nematoid worms in the living human subject also. See **CELYSTRIA**; and **FILARIA SANCTI-JOHNIS**.
T. S. CORROLD.

HÆMATURIA (*αἷμα*, blood, and *οὐρ*, urine).—**STON.**; Fr. *Hématurie*; Ger. *Blutharnen*.

DESCRIPTION.—Hæmaturia is a symptom of many different morbid conditions of the system, and of the urinary tract. The quantity of blood discharged in the urine varies greatly, and the appearance of the urine corresponds. Sometimes it is dark, loaded with clots; sometimes it is merely smoky, or of a faintly pink hue. It is albuminous, and corpuscles (often altered by soaking in the urine) may be discovered by the microscope, sometimes becoming swollen, sometimes shrunken. The following are the best tests for detecting the presence of blood in the urine.—1 *Guaicum*. When equal parts of tincture of guaiacum and oil of turpentine are shaken together to make an emulsion, and the urine is cautiously added, an intense blue colour is produced if blood be present. 2 *Spectrum analysis*. Very minute quantities of blood in the urine show absorption-lines between Fraunhofer's lines D and E in the yellow and green of the spectrum. See **SPECTROSCOPY**.

The blood in hæmaturia may be derived from the urethra. If so, it precedes the stream of urine, sometimes forms a long thin clot, and may escape in the intervals of micturition. Sometimes it is derived from the prostate gland or the bladder. When it has lain in the bladder and been poured out in considerable quantity, it is often in clots, and when the urine is voided, the first part is frequently clear, the last loaded with blood. Blood may also be derived from the ureter or the pelvis of the kidney. Sometimes clots in the form of moulds of these structures may be recognised. At other times the blood is derived from the substance of the kidney, and then is intimately mixed up with the urine, which frequently exhibits bloody tinge-casts.

ETIOLOGY AND PATHOLOGY.—Urethral hæmorrhage is due to local inflammation or rupture of vessels. Prostatic hæmorrhage may be due to malignant disease, to tumours, to inflammation, or to scrofulous affection of that organ. Vesical hæmorrhage results from malignant disease, from simple villous growth, inflammation, ulceration, tubercular disease, or the irritation of calculus. Hæmorrhage from the ureters or pelvis of the kidney may be due to the presence of calculi, or to unexplained causes. Hæmorrhage from the kidney may be due to cancer, tubercle, suppurative nephritis, or to the irritation of crystals or anamorphous concretions within the uriniferous tubules. Hæmorrhage occurs also in all the forms of Bright's disease, especially in the early stage of the inflammatory form, and the advanced stage of the cirrhotic. It results moreover from over-doses of turpentine and cantharides, and from rupture of the kidney. Sometimes it is a manifestation of purpura hæmorrhagica, more rarely of scorbatus; and occasionally it occurs in the course of, or as a sequel of eruptive or continued fevers. It is also occasionally recurrent. Renal hæmorrhage occurs in Egypt, Mauritius, and other localities,

In consequence of the presence in the pelvis of the kidney of a minute parasite, the *Bilharzia hæmatobia*; or of the presence in the blood of the *Filaria sanguinis-hominis*. See *BILHARZIA*; *CHYTRIA*, and *FILARIA SANGUINIS-HOMINIS*.

TREATMENT.—The treatment of hæmaturia must vary according to the lesion to which the hæmorrhage is due, but where the symptom is so urgent as to demand treatment for itself, the most important points to be attended to are rest; free relief of the bowels, the application of ice-bags over the source of the hæmorrhage; along with the internal administration of astringents, especially gallic acid, ergot of rye, perchloride or persulfate of iron, turpentine, or acetate of lead, with or without opium. If these do not succeed, the subcutaneous injection of ergotine is often efficacious. Surgical interference may be required for relief of symptoms due to coagula.

T. GRAINGER STEWART.

HÆMIC ASTHMA.—A form of asthma, dependent upon an abnormal condition of the blood. See *ASTHMA*.

HÆMIC MURMUR.—A murmur connected with the condition of the blood, as in *ANÆMIA*. See *ANÆMIA*, and *PHYSICAL EXAMINATION*.

HÆMIN.—See *HÆMOGLOBIN*.

HÆMOGLOBIN (*αμα*, blood, and *globus*, a ball). **SYNON.**—Hæmatoglobulin, Hæmato-crystallin, Cruorin (Stokes).—This substance, which is of great physiological interest, is of an extremely complex nature, being a compound of two bodies, the one a protein known as globulin or globin; and the other a nitrogenous derivative called hæmatin. These two substances are combined in the proportion of 87·5 per cent of globulin to 12·41 per cent of hæmatin (Schmidt), and the provisional formula of hæmoglobin, according to Hoppe-Seyler, is $C^{100}H^{100}N^{134}Fe^{23}O^{177}$. If we estimate the red corpuscles as forming about 32 per cent. of ordinary blood, hæmoglobin may be considered as forming 13 to 14 per cent. of the same blood.

Hæmoglobin presents a singular exception to the general law of diffusion, inasmuch as, though it readily crystallises, it will not diffuse through membranes as such without decomposition. A considerable variety in the shape of the crystals is met with in different animals, in man they occur as elongated prisms.

The most important property of this compound is its affinity for oxygen. In some obscure manner this gas enters into a loose combination with hæmoglobin, forming *oxy-hæmoglobin*; and in then conveyed by the red corpuscles throughout the body; separating again from its conveyer in the tissues. The hæmoglobin thus deprived of its oxygen is known as *reduced hæmoglobin*, and is of a purplish colour, whilst the *oxy-hæmoglobin* is of a scarlet tint. It is thus that the difference in colour between arterial and venous blood is mainly to be accounted for. It is to be noted that whatever be the nature of the combination that exists between the oxygen and its carrier, it is such that the gas retains its properties as a gas, and the union may be roughly compared to a mere solution of the gas in a fluid. The recent experiments of Malassez, Hayem, Gowers, and others have furnished

us with means of estimating within very reasonable limits the quantity of red corpuscles contained in any sample of blood (see *HÆMATOCRITISM*); and further by a comparison of its colour with that of a solution of known strength the percentage of hæmoglobin in it may be ascertained with tolerable accuracy (see *HÆMOCONCENTRATION*). We are as yet unacquainted with the variation in its amount in the majority of diseases, but a very considerable diminution, even to the extent of 25 per cent, has been met with in chlorosis. Whether with the alteration in quantity of hæmoglobin there is any change in its composition is uncertain, from the improvement following the administration of iron in certain cases of anæmia it would seem that there may be. As regards the iron constituent of this compound, amounting to 4 or 5 per cent., it has been suggested, although on no very good grounds, that the oxygen-carrying property is due to this element. It is noticeable that in some of the lower animals copper has been met with, taking the place of iron.

From a pathological point of view, hæmoglobin is chiefly of interest in respect to its derivatives, which are easily obtained by the action of heat, acids, alkalies, &c., and also on account of the relationship that exists between this substance and the various pigments met with in the body. The chief derivatives of hæmoglobin, namely, hæmatin, hæmatoidin, and hæmin, will now be described.

Hæmatin.— $C^{80}H^{70}N^{20}Fe^{10}O^{16}$ (Hoppe-Seyler). Hæmatin may be obtained from red blood corpuscles by treatment with alcohol, acidulated with sulphuric acid.

Hæmatin is an amorphous dark-brown powder. A solution gives a characteristic absorption-band in the spectrum, different from those produced by hæmoglobin. It gives a green solution when boiled with caustic potash.

Hæmatoidin (*αμα*, blood, and *elōs*, appearance). ($C^{110}H^{120}N^{20}O^{20}$).—Hæmatoidin may be prepared from hæmatin by the action of acids, which remove the iron. This substance is crystalline (rhombic prisms or needles), and of a red or greenish-red colour, a fact which shows that the colour of hæmoglobin is not dependent on the iron. It is of considerable pathological interest, being frequently found in old clots, and in the cavity of ruptured Graafian follicles; it is the cause also of the staining so often seen in the neighbourhood of extravasations of blood, varying from lemon yellow up to reddish black.

Hæmin ($C^{80}H^{70}N^{20}Fe^{10}O^{16} \cdot 2HCl$).—Hæmin, which may be prepared from dried hæmoglobin by treatment with glacial acetic acid, in the presence of an alkaline chloride, is a hydrochloride of hæmatin. It crystallises tolerably readily in needles or rhombic plates, and thus becomes an easy means of detecting the presence of blood in stains of a doubtful nature.

The relationship of hæmoglobin, hæmatin, hæmatoidin, and hæmin to the pigments of the body is of the greatest interest. It would seem that the hæmoglobin is the source of all—biliary, urinary, &c. Bilirubin is closely allied to, if not identical with, hæmatoidin; and a play of colours—the result of oxidation—may be obtained from the latter when treated with nitric acid, similar to that produced by the bile-pig-

ments under the same condition. The injection of hæmoglobin into the blood is followed by the presence of bile-pigments in the urine, and an increase of bilirubin in the bile. Melanin, the black pigment often found in connection with new-growths, especially with those of a malignant character, also appears to be directly drawn from hæmoglobin. The colouring matter of the blood is obviously associated, in some way other than that of its oxygen-carrying function, with the nutrition of the tissues, in connection with the obscure but unquestionable influence of pigments. W. H. ALLCHIN.

HÆMOGLOBINOMETER (Hæmoglobin; and *meter*, a measure).—**DESCRIPTION**.—An instrument for the clinical estimation of the amount of hæmoglobin in blood.

DESCRIPTION.—The estimation of hæmoglobin may be ascertained by estimating the amount of iron in the blood, or the amount of dilution necessary to obscure a certain absorption-band in the spectrum (see **SPECTROSCOPE**). Neither of these methods is, however, available for clinical use. Simpler methods have therefore been contrived, which proceed by comparing the colour of diluted blood with that of solutions of carmine and picricurmine. By this combination the tint of blood and even its spectrum may nearly be obtained (Malassés). Coloured discs have been employed for the same purpose (Hayem). In these methods a given dilution of blood is made, and this is compared with the tint of the standards. In the hæmoglobinometer designed by the writer (and made by Hawksley) the blood is progressively diluted until it reaches the tint of a standard the colour of which corresponds to a dilution of 1 part of healthy blood in 100 of water. The degree of dilution necessary to make the two correspond represents the amount of hæmoglobin. The apparatus consists of two tubes of exactly equal diameter, and a capillary pipette, holding 20 cubic mm., for measuring the blood. One tube is filled with a standard, consisting of glycerine jelly coloured to the required tint. The other is graduated, each division being equal to the volume of blood taken (20 cubic mm.), so that 100 divisions equal 100 times the volume of blood. The dilution is made by a pipette stopper, and the number of degrees of dilution necessary indicates the percentage proportion of the hæmoglobin of the blood examined to normal blood. For example, the blood of a patient being progressively diluted, is found to reach the tint of the standard when the amount of water added corresponds to 45 degrees of dilution; the blood examined therefore contains 45 per cent. of the normal quantity of hæmoglobin. W. R. GOWANS.

HÆMOPERICARDIUM. See **HÆMATOPERICARDIUM**.

HÆMOPHILIA (*αἷμα*, blood, and *φίλη*, predisposition for).—**SYNON.**: Hæmorrhaphilia, Hæmorrhagic diathesis. Bleeders; Fr. *Hémophilie*; Ger. *Bluterkrankheit*.

DEFINITION.—A congenital disease, often hereditary, characterised by a tendency to immoderate bleedings, whether spontaneous or traumatic, and to obstinate swellings of the joints.

ÆTIOLOGY.—Men are far more liable than women to this disease; the proportion being

about eleven to one. Women who suffer from hæmophilia show much less typical specimens of the disease than men, and rarely die from hæmorrhage, although floodings and profuse menstruation are common.

The best-ascertained cause of hæmophilia is hereditary predisposition. No other cause is known with anything like certainty. In a bleeder family, the disease descends to the boys through the mothers, the women remaining quite healthy and apparently free from all disease. The fathers do not seem to transmit the disease to their sons, at least, instances of this are rare. The women of bleeder families are remarkably fertile. Some have thought this disease to be more common in Germany, but this is probably owing to the greater attention paid to the disease in that country. Cases have been met with in the Indian Archipelago, North America, the Scandinavian kingdoms, and elsewhere. The disease is not limited to the Aryan races, as the Jews, a Semitic nation, are singularly liable to it.

ANATOMICAL CHARACTERS.—No morbid appearances have yet been found after death with any consistency. The blood-vessels examined with the microscope have shown no change. The blood is apparently unaltered. Yet it is most probably the vessels which are at fault; as in most of the other hæmorrhagic diseases about which much is known, the vessels have been found diseased. The swellings of the joints appear to be due to the extravasation of blood within the articulation.

SYMPTOMS.—The first signs of hæmophilia are commonly seen during the first year of life; but sometimes they are delayed until the beginning of the second dentition. Cases on record of a much later appearance of the first symptoms are not trustworthy. It is very rare for bleedings to be noticed at birth. There is nothing about the subjects of hæmophilia, when not suffering from bleeding, to distinguish them from ordinary persons. They look well, and nothing amiss can be discovered by physical examination in chest or belly. It is stated, also, that the boys have often good ability and do well at school.

There are three well-marked degrees of hæmophilia. The first is the most typical and characteristic, in which there is a tendency to every kind of hæmorrhage, traumatic or spontaneous, interstitial or superficial. The swelling of the joints is well-marked. This degree is scarcely ever seen in women, but it is the most common among men. In the second degree, spontaneous hæmorrhages from the mucous membranes only are present. The third degree, in which the tendency is little marked, is seen only amongst the women of bleeder families, and shows itself only by spontaneous ecchymoses.

Hæmorrhage.—Spontaneous bleedings are sometimes preceded by prodromæ. These are symptoms of unusual fulness and plethora. The mucous membranes supply the blood in this case; in childhood bleeding from the nose being the most common, and also the most fatal, although bleedings from the bowel, mouth, or chest may also occur. There is only one known instance of death from hæmaturia. The traumatic bleedings vary much in intensity, even in the same individual. Death has followed division of

the frenum of the tongue, vaccination, leeching, and the extraction of a tooth. This last is a very common cause of death, and ought never to be undertaken in hæmophilia. If abscesses be opened, furious bleeding commonly takes place, and the same occurs if a blood-tumour or extravasation of blood be interfered with.

The bleeding is nearly always capillary, and may kill in a few hours or after some weeks. The quantity of blood lost is sometimes enormous. After the bleeding the patients are extremely anæmic; and this state may last for months.

Besides superficial bleedings, interstitial hæmorrhages, ecchymoses, and blood-tumours may be observed, whether spontaneous or traumatic. A bruise which a healthy person would not feel may fill the connective tissue of a limb with blood; or the bleeding may be circumscribed, and form a tumour instead.

Swelling of the joints.—This chiefly affects the larger joints, the knee being most commonly attacked. The joint, most commonly after some injury, becomes swollen and painful, and apparently filled with fluid, there is fever; and this state may last for many weeks, and is very apt to relapse during convalescence.

DIAGNOSIS.—The diagnosis of hæmophilia is often easy. If a boy have suffered repeatedly from early infancy from abundant bleedings—especially traumatic—and from joint-affections, there can be no doubt of the diagnosis. It is made more certain by the existence of hereditary predisposition. In women the diagnosis must be made with more care, as they are subject to a hæmorrhagic disorder which first appears about puberty, but which is not hereditary.

PROGNOSIS.—The prognosis is bad as regards complete recovery, though not so serious with respect to life as was formerly thought.

TREATMENT.—In the treatment of the bleedings of hæmophilia, styptics are of little use. The spontaneous form should not at first be interfered with, but the traumatic may often be stayed at its first onset by the judicious use of compression. The tincture of perchloride of iron seems the best internal remedy. In the last resort, transfusion may be had recourse to. In the intervals of hæmorrhages meat diet, cod-liver oil and steel, and residence in a warm climate, are the most appropriate remedies. All surgical or medical procedures by which blood is drawn must be strictly avoided. There are, however, only two instances on record of disagreeable consequences following vaccination. Marriage should be forbidden, especially to women who do not themselves suffer from the disease, but belong to bleeder families.

The joint-affection must be treated chiefly by rest and the application of splints.

J WICKHAM LENO.

• **HÆMOPTYSIS** (*æ-læ*, blood, and *rrhœ*, I spit)—*SYNON.*: PNEUMORRHAGIA; BRONCHORRHAGIA; *Fr.* *Hémoptysie*; *Ger.* *Bluthusten*.

DEFINITION.—Blood-spitting having its source in pulmonary or bronchial hæmorrhage.

The restriction of the term hæmoptysis, as thus defined, has the sanction of long usage and convenience. Hæmorrhage from an aneurism open-

ing through the lung or air-passages would not strictly be included in such a definition.

Spitting of blood when it arises from other and less important sources comes under the denomination of *falsæ* or *spurious hæmoptysis*.

ÆTIOLOGY and PATHOLOGY.—The causes of hæmoptysis in the widest sense of the term, and having regard to its pathology, may be thus enumerated:—

I. Hæmorrhage from the pulmonary artery or its radicles.

1. Rupture or wound of the lung from external violence.

2. Active hyperæmia of the lungs—inflammatory, vicarious, or induced by violent effort or excitement. The active hyperæmia may be primary as regards the lungs; or may supervene or be attendant upon disease already present in them.

3. Mechanical hyperæmia of the lungs, secondary to heart-disease, or embolism of one of the pulmonary branches, or to pressure from tumours, such as enlarged bronchial glands (*see* BRONCHIAL GLANDS, Diseases of).

4. Necrotic division of vessels in the course of softening of tubercular or other consolidations in destructive lung-diseases—phthisis, tuberculosis, cancer.

5. Aneurismal dilatation or simple erosion of branches of the pulmonary artery, exposed in the course of excavation of the lung, or ulceration of the bronchial mucous membrane.

6. Primary aneurisma of the pulmonary artery within the lung.

II. Hæmorrhage from the bronchial capillaries.

Capillary hæmorrhage from the bronchial mucous membrane

III. Hæmorrhage from the aorta, or one of its great branches.

Aneurism rupturing through the lung or into a bronchus.

Details respecting the pathology of these several forms of hæmoptysis will be found under the headings of the principal diseases giving rise to them. There are a few additional remarks, however, that should be introduced here.

The pathology of hæmoptysis occurring in early phthisis of which it is one of the most frequent symptoms—is still somewhat obscure. Besides the active hyperæmia above referred to, that is, the inflammatory congestion that constitutes the first stage of some kinds of phthisis, and tends to recur at different periods of the disease; besides also the necrotic division of vessels, or their aneurismal dilatation, which more especially account for the hæmorrhage occurring in the later stages of the disease; there are other conditions present in early phthisis which probably have much to do with the occurrence of hæmoptysis. The minute blood-vessels are importantly concerned in the very earliest stage of phthisical lung-disease in one or other of three ways:—

(a) Their walls become the seat of nuclear proliferation, and hence become softened; and (b) these vessels become more or less extensively blocked, not merely as the result of the inflammatory *stasis* which may affect their capillaries, but by the pressure of surrounding tubercles

growth. (c) It is very possible that in the ill developed lungs of small-chested people, who inherit a tendency to consumption, the vessels are also morbidly frail, and are apt to give way in any temporary hyperæmia. Some persons are remarkably subject to irregular distribution of blood; they are liable to chills, cold extremities, and transient flushings; and a *pulmonary blush* is as conceivable as a temporary flush elsewhere, and would favour the occurrence of hæmorrhage.

It has been alleged that the hæmoptysis occurring in all stages of phthisis frequently has its source in hæmorrhage from the bronchial tubes, and that this bronchial hæmorrhage may give rise secondarily to phthisis, or may, when it occurs in the course of that disease, set up fresh centres of mischief in the lungs by inhalation of blood to distant portions. In the entire absence of reliable pathological grounds for this view, and in the abundance of anatomical evidence, clinical experience, and weight of authority in favour of the pulmonary origin of hæmoptysis, we are, in the opinion of the writer, justified in believing that decided hæmoptysis originating in hæmorrhage from the bronchial mucous membrane is exceedingly rare, excluding, perhaps, syphilitic ulceration of the bronchi. Blood inhaled to distant portions of lung may, however, as shown by Dr Ragnall Thompson, undergo changes resulting in fresh pulmonary destruction.

DESCRIPTION.—The quantity of blood brought up in hæmoptysis varies from a mere streak to two or three quarts. When blood is expectorated in large quantity, it is pure and unmixed; and either dark and venous, or bright arterial. The first and last portions are usually more or less aerated. If in small quantity, the blood is most generally bright and frothy, it may be only a speck or two upon the sputum, or it may be in several mouthfuls of pure aerated blood. It commonly happens that this mitigated and more characteristic hæmoptysis precedes the rarer attack of profuse hæmorrhage that may prove instantly fatal. Hæmoptysis is sometimes scanty, dark, and clotted, usually from a small portion of blood having been detained in the lung before being expectorated.

In decided hæmoptysis the shock to the system is always great. The patient is alarmed and anxious, especially on the first attack. The sense of weakness and prostration is, indeed, often prolonged after the attack—not necessarily a severe one as regards quantity of blood lost—has ceased. The face is often flushed, the extremities cold. The temperature is usually depressed; after a few hours it becomes normal, and it may continue so, or it may rise in the course of forty-eight hours or within five days. This elevation of temperature may depend (a) upon return of the previous fever after being temporarily checked by hæmorrhage; (b) upon the cause which has also produced the hæmoptysis; or (c) upon the secondary consequences of the hæmorrhage. It has been clearly shown that the inhalation of blood into the bronchial tubes and pulmonary alveoli sometimes sets up broncho-pneumonia, and thus may give rise to fresh centres of phthisical disease. The later rise of temperature up to the fifth day, the more reason we have for regarding it as due to secondary pneumonia.

ANATOMICAL CHARACTERS.—These depend very much upon the nature of the disease which has preceded the hæmoptysis. In cases of death from hæmoptysis there are the usual appearances—pallor of organs, empty and contracted ventricles, &c.—of death from hæmorrhage. The bronchial tubes of both lungs are found to contain clots. The healthy portions of lung are found inflated from obstructions in the bronchi, impeding the exit of air; they are generally pale, but beautifully speckled by pink spots, marking the lobules into the air-cells of which blood has been inhaled. If death take place several days after profuse hæmoptysis, any blood which remains in the bronchi is dark and disorganised, and patches of consolidation may sometimes be found, having for their centres the stained appearance attributable to inhaled blood. More or less bronchitis is also noticeable. It is rare to find fatal hæmoptysis without the presence of cavities, which are also, more or less, filled with blood-clot. In almost every instance of fatal hæmoptysis in phthisis, sufficient diligence will discover either an aneurism of a pulmonary vessel within a cavity, or ulcerative erosion of an exposed vessel. The writer has found such a condition in fifteen cases at various ages, including one infant seven months old.

SIGNIFICANCE OF HÆMOPTYSIS.—No modification in our views respecting the nature of phthisis can lessen the significance of hæmoptysis as being one of its most important positive signs. Thus regarded, it is a warning that may sometimes save, and very often prolong life, by drawing our early attention to a condition that might otherwise remain too long concealed; but, lightly considered and carelessly treated, it is but the precursor of destructive disease.

DIAGNOSIS.—Genuine hæmoptysis can rarely be mistaken by a skilled observer present at the attack. The gurgling in the bronchi, the loose cough, and repeated expectoration of *bright frothy* blood are quite characteristic. The blood is distinctly expectorated with cough, not vomited; and its quality is distinctly fresh, not changed. In hæmatemesis, with which hæmoptysis is sometimes confounded, the blood is brought up by vomiting, is more or less mixed with the contents of the stomach, and, save when the hæmorrhage is very rapid and abundant, presents a dark grumous appearance, owing to the action of the gastric fluid upon it (see HÆMATHEMESIS). It may, too, be observed that the blood does not come from the nose, unless a small quantity be projected through the nostrils with the spasmodic cough. If, as often happens, no medical attendant is at hand at the moment of the attack, the appearance of the blood is usually sufficient for diagnosis; and if the hæmoptysis have been at all copious, any further expectorations for the next few hours are sanguineous. The fact of this sanguineous colouration of the sputa having existed for some hours, or a day or two after an hæmoptysis, is positive evidence of the hæmoptysis having been genuine. In cases of *very copious* hæmorrhage from a large pulmonary branch, the blood brought up is dark and venous.

It is very important in investigating the cause of hæmoptysis to be as gentle as possible in physical examination. We can listen to the

lungs in front and to the heart without moving the patient or requiring him to breathe deeply; we can make a note of the temperature; and at the time we should do no more.

The throat should always be examined in doubtful cases of hæmoptysis, as the blood will sometimes be found to have issued from an ulcerated tonsil, or even from enlarged vessels on the posterior wall of the pharynx. *Spiræus hæmoptysis*, however, may be defined as the escape of a blood-stained mucus from the throat or gums. In cases of *spiræus hæmoptysis* there is usually distinct evidence of a morbid condition of these parts. The mucous membrane of the fauces is relaxed, the gums are spongy, and often bled when the teeth are brushed in the morning. Sometimes this condition of gums arises from insufficient attention to the teeth; carious stumps and much tartar round the teeth causing irritation and sponginess of the gums. The patients are usually anæmic and short-breathed, and often complain of morning cough, but there is no evidence of lung-disease. The blood-stained mucus is usually ejected in the morning, on waking, and often escapes from the mouth during the night, staining the pillow. On examination, it is found to be a pink, watery mucus, uniformly stained, and containing comparatively few blood-corpuscles.

TREATMENT.—Absolute rest is the first thing to be observed in the treatment of all attacks of hæmoptysis. The patient should lie down with the head and shoulders raised by pillows. He should not talk. The room should be kept quiet and cool, the bed-clothes should be light, but sufficient, and warmth should be applied to the feet. A little ice in the mouth, or some iced water to sip, will ease the cough and tend to check hæmorrhage. The patient must, if possible, be reassured as to the absence of present danger, and the shock to the system allayed without the use of stimulants. Sometimes opium may be usefully given for this purpose, due regard being had to the habits and idiosyncrasies of the patient. Astringent medicines are not always needed in hæmoptysis, especially in attacks in which the hæmorrhage is presumably capillary; they may, however, be given in such cases in small doses. To be really useful in hæmoptysis, astringents must be given in full doses. Those most used are acetate of lead, four grains, every three or four hours; alum, twenty grains, with dilute sulphuric acid, thirty minims, every four hours; gallic acid, twenty to thirty grains every half-hour or hour, for two or three doses, followed by ten-grain doses every three hours, oil of turpentine, thirty minims every two hours in sweetened mucilage or in milk, for a couple of days, then in half or third doses, liquid extract of ergot in half-drachm or drachm doses, every two or three hours; ten- or fifteen-minim doses of the pernitrate or persulphate of iron solution, or thirty or forty minims of the perchloride freely diluted. Of the above-mentioned astringent remedies, alum and sulphuric acid, gallic acid, and ergot are the best in the greater number of cases. Acetate of lead is less applicable to cases of lung-hæmorrhage than in bowel or kidney lesions. Ergot is to be preferred in those cases in which we infer that a considerable vessel has given way. It may also be given in the form of

ergotin— $\frac{1}{2}$ to 2 grains hypodermically; but thus given it sometimes causes much local inflammation. Oil of turpentine is certainly one of the most powerful of astringents in pulmonary hæmorrhage, and may be usefully held in reserve. When freely administered the condition of the urine must be carefully noted. Cases of hæmoptysis only rarely occur in which it is well to give the iron astringents. As a rule they tend to increase pulmonary congestion; but in some cases, in which hæmoptysis has a tendency to continue after the patient has been brought to a state of profound anæmia from the first outburst, they may be usefully given, their effect being carefully watched. Digitalis is a drug sometimes of great value in hæmoptysis; it is best adapted to those cases in which there is much excitement of circulation. In cases, for instance, in which the hæmoptysis has been determined by intemperance, or in full-blooded people by effort, tincture of digitalis in twenty- or thirty-minim doses may be given. In such cases, in which the portal system is usually congested, sulphate of magnesium and dilute sulphuric acid may be combined with the digitalis, and given every four or six hours for a couple of days or so. In the treatment of hæmoptysis it is usually necessary to counteract the effect of the astringent upon the bowels by purgatives or laxatives. An enema may be necessary to enable the bowels to act easily and without straining. The use of the bed-pan must of course be enjoined.

Counter-irritation is of great value in the treatment of many cases of hæmoptysis, chiefly in those cases in which the hæmorrhage is not great, and occurs in the course of phthisis, being due either to local pulmonary congestion, or to active hyperæmia of the walls of a cavity. Blisters are, as a rule, best avoided in copious hæmoptysis during the stage of shock. Continuous cold to the chest is decidedly to be deprecated. The intermittent application of cold may sometimes be employed, but is a measure of doubtful expediency.

The temperature and pulse of the patient should be carefully watched during an attack of hæmoptysis, and for a few days afterwards.

The diet must at first be restricted to cold nutritious fluids; stimulants, except in special cases, must be interdicted.

The treatment of *fusus* or *spiræus hæmoptysis* depends upon its cause. In most cases the cause being anæmia, with a relaxed and morbid condition of mucous membranes, an acid preparation of iron containing some chloride of potash and glycerine will speedily cure the malady. When the gums are spongy, the addition of finely powdered kino or catechu to a chalk or charcoal tooth-powder, or the addition of some glycerine of tannin to the tooth-water, will prove efficacious. Astringent gargles will suggest themselves in fitting cases; and fruit and vegetables must be added to the diet. R. DOUGLAS POWELL.

HÆMORRHAGE (*æmæ*, blood, and *pyrrhos*, I burn forth).—**SYNON.**: *Fr.* Hémorrhagie; *Ger.* Blutfluss.

DEFINITION.—The escape of blood from any part of the circulation, and its discharge from the body.

When blood escapes from any of its arterial

reservoirs, it is either extravasated into the neighbouring organs or cavities, or flows from one of the surfaces or orifices of the body. In the latter case only is the term 'hæmorrhage' strictly applicable (see *EXTRAVASATION*). This distinction, however, is not always carefully observed; and such expressions as 'cerebral hæmorrhage,' 'hæmorrhage into the pericardium,' and 'hæmorrhagic eruptions' are applied in connection with what are more correctly called *extravasations* of blood.

ÆTIOLOGY.—Hæmorrhage is almost always due to a solution of continuity of some part of the circulatory system, whether by injury or by disease. Hæmorrhage from the external surface of the body is, with few exceptions, the result of wounds or other form of injury, but ulceration—either simple or malignant—frequently lays open a vein or an artery, and aneurism of the great vessels, and even of the heart, may also give rise to external bleeding. Hæmorrhage from internal organs, on the contrary, is most frequently the result of disease, as, for instance, ulceration or aneurism, or of circulatory disturbance, such as congestion. Great excitement or severe exertion is one of the chief determining causes of hæmorrhage, by producing great or sudden rise of the general blood-pressure, whether by cardiac disturbance or by obstruction of the terminal vessels, and may even lead to the rupture of healthy vessels. Local disturbances of the blood-pressure give rise in the same way to congestion or hyperæmia and finally to hæmorrhages. The principal causes of hæmorrhages of this class are diseases of the heart, of the great vessels, of the respiratory organs, and of the liver, and sudden variations in the atmospheric pressure or in the temperature; and such hæmorrhages are also in some instances undoubtedly of a *viscous* nature. Certain conditions of the blood are believed to predispose to hæmorrhage, as, for example, in scurvy, purpura, the malignant fever, chronic Bright's disease, and alcoholism. There is, probably, however, a lesion of the vessel-walls in some of these diseases. A peculiar condition of body is known as the *hæmorrhagic diathesis* or hæmophilia; the subjects of which exhibit, amongst other forms of debility, a remarkable tendency to profuse hæmorrhage from trivial causes. See *HÆMOPHILIA*.

SITES AND VARIETIES.—Bleeding from the surface of the body, whatever its origin, is simply called *hæmorrhage*, and its exact source and situation are otherwise defined. On the other hand, when blood escapes by any of the natural openings of the body, and is derived from an internal organ, the hæmorrhage is described by a special name. Hæmorrhage from the nose is called *epistaxis*; from the ear *otorrhagia*, from the stomach *hematemesis*; from the respiratory tract *hemoptysis*; and from the urinary tract *hematuria*. Blood passed *per anum*, after undergoing certain changes to be referred to immediately, is called *melæna*. *Menorrhagia* and *metrorrhagia* are the names given to profuse bleeding from the genital organs in the female, at the menstrual period and at other times, respectively.

DIAGNOSIS.—The local phenomena that characterize hæmorrhage from the external parts of the body, vary with the source of the blood. If

it proceed from an artery of considerable size, it escapes in the form of a jet, which is strengthened at such least of the pulse as an active spurt. Blood discharged from an opened vein either flows in an abundant continuous stream, or wells up from the depth of the tissues in which the vessel lies. Capillary hæmorrhage is generally much less profuse, and is most frequently seen in the form of oozing. Blood proceeding from internal organs is variously discharged by the several outlets. Sometimes it is immediately expelled, especially if in quantity; or it may escape even when in small quantity, owing to gravitation, as in hæmorrhage from the nose. Most frequently the blood is retained for a time, and then, acting as a foreign body, is ejected, for example, in bleeding from the stomach, bowels, or bladder.

CHARACTERS.—Blood flowing from the surface of the body usually presents its familiar characters. The colour of the blood will be scarlet when it is derived from an artery; purple, with a tendency to become scarlet on the surface, when it flows from a vein; and of a tint intermediate between these two colours when the hæmorrhage is capillary. In all cases, the blood coagulates more or less abundantly around the seat of hæmorrhage.

In hæmorrhage from internal organs, on the contrary, the blood is frequently coagulated; more or less mixed with the fluids of the part; or otherwise altered during its transit. The following are the principal changes that blood undergoes in its passage towards the several outlets of the body:—

Blood flowing from the *external ear*, or from the *anterior nares*, is frequently thin and watery, if the hæmorrhage have lasted for any length of time. Blood discharged from the *posterior nares* is often coagulated, black, and mixed with thick mucus. In hæmorrhage from the *mouth*, the blood may be derived from that cavity, from the fauces, from the respiratory passages; or from the upper portion of the digestive tract—especially the stomach. When the blood flows from some part of the *mouth*, such as the gums, tongue, palate, or cheeks, it is more or less intimately mixed with frothy saliva and mucus. In hæmorrhage from the *respiratory passages*, or from the *stomach* through the mouth, the ejected blood varies extremely in different instances. Hæmorrhage from the *genito-urinary tract* is also specially described. Hæmorrhage from the bowels is not peculiar, if the source of the blood be near the anus, or if the bleeding be very profuse, taking the form sometimes of a gush of fresh, warm blood at other times of a mere red streak upon the feces. If the blood be derived from a higher part of the intestine, the appearance of it, when discharged, will be different. Generally it is so far altered by the action of the various intestinal contents, as to be converted into a black tarry-looking mass (see *MELÆNA*). Less frequently, the bleeding may be so profuse as to fill a considerable part on of the bowel, and clots of blood may then be passed, as in some cases of hæmorrhage in typhoid fever. The peculiar characters of *menstrual* blood are described elsewhere. Hæmorrhage from the *uterus* in large quantity consists of unaltered blood, whether coagulated or not.

COURSE AND TERMINATIONS.—Hæmorrhages caused by wounds are generally most profuse at first; and, unless they prove fatal speedily, or are artificially arrested, gradually cease. On the contrary, hæmorrhages due to disease are frequently insignificant at first, and increase in amount; or they recur again and again in variable quantity.

Many natural causes contribute to the arrest of hæmorrhage, the most important being—weakening of the force of the heart by the loss of blood, the contraction of the coats of the vessels at the seat of lesion; the coagulation of the blood—first around, and then within the open vessel, the pressure of the extravasated blood in the surrounding tissues, and the increased coagulability of the blood after the flow has continued for some time. The relief of the local disturbance of pressure by the occurrence of the hæmorrhage, is alone sufficient in many instances to arrest the flow.

EFFECTS.—The effects of hæmorrhage are chiefly exerted upon the system generally, and they are therefore remarkably uniform, whatever may be its locality. The circumstances that more especially affect the intensity of the effects or symptoms are two, namely, the amount of blood lost, and the rapidity of the flow. When hæmorrhage is at once free and persistent, syncope rapidly ensues, probably accompanied by convulsions, and ending speedily in death unless the bleeding either spontaneously ceases, or be artificially arrested. The sudden loss of one half of the total amount of blood in the body (say five pounds) is said to be sufficient to cause death. On the other hand, enormous quantities of blood may be lost without a fatal result if the hæmorrhage be slow, or frequently repeated with considerable intermissions. The condition of the subject of the hæmorrhage then becomes one of *anæmia* (see *ANÆMIA*). More moderate bleedings frequently repeated produce faintness, and may cause a certain degree of pallor, which shortly disappears. Moderate hæmorrhages from certain situations, for example from the nose, rectum, or even the lungs, may sometimes relieve congestion, and be attended with great relief and benefit.

Local effects do, however, occur in some forms of hæmorrhage. Hæmoptysis may be accompanied by inhalation of blood, and lead to inflammation or more complex disease of the lungs. Hæmorrhage into the uriferous tubules causes plugging of these, and discharge of blood-casts. Blood retained in the generative or in the respiratory passages occasionally becomes decomposed. The special symptoms of the several forms of hæmorrhage are described under the head of each.

TREATMENT.—The treatment of hæmorrhage from external parts is a subject of purely surgical interest, but it may be said that, in cases of emergency, moderate pressure with the finger or other means, on the seat of the bleeding, is generally practicable and successful. Hæmorrhage from internal parts requires special treatment according to the particular organ from which it is proceeding. The reader is, therefore, referred to the several articles on *EPISTAXIS*, *HÆMATHEMESIS*, *HÆMATURIA*, *HÆMOPTYSIS*, *MELENA*, and *MEN-*

STRUATUM, Disorders of; as well as to the articles on *HÆMOSTATICS*, and *STYPTICS*.

J. MITCHELL BATON.

HÆMORRHAGIC (*αἷμα*, blood, and *ῥαγναι*, I burst forth).—Associated with hæmorrhage. The word is applied to certain inflammatory products or to effusions when they contain blood, as in *hæmorrhagic peritonitis*; and to varieties of certain diseases in which extravasations or hæmorrhages from free surfaces occur, for example, *hæmorrhagic small-pox*, *hæmorrhagic measles*, and *hæmorrhagic purpura*.

HÆMORRHAGIC DIATHESIS. See *HÆMOPHILIA*.

HÆMORRHOIDS (*αἷμα*, blood, and *ῥαῖ*, I flow).—**SYNON.**: Piles; Fr. *Hémorrhoides*; Ger. *Hämorrhoden*.

DESCRIPTION.—The hæmorrhoidal veins distributed to the lower part of the rectum are very liable to become dilated and varicose, giving rise to a disease termed *hæmorrhoids* or *piles*. When the plexus beneath the mucous membrane within the external sphincter is thus affected, the hæmorrhoids are said to be *internal*. When the veins beneath the integuments outside the muscle are enlarged, the hæmorrhoids are called *external*. Internal and external hæmorrhoids very frequently co-exist.

External Hæmorrhoids.—We may distinguish two kinds of external piles:—(1) A *sanguineous tumour*. (2) A *cutaneous excrescence* or outgrowth.

(1) The *sanguineous tumour* consists of a softish elevation of the skin near the margin of the anus, of a rounded form, and a livid or slightly blue tinge. On cutting into it, we find a dark-coloured coagulum enclosed in a cyst.

(2) The *cutaneous excrescence*, or second form of external pile, consists of a flattened prolongation of skin, due to hypertrophy of the epidermis, papillæ, and cutaneous layers. It is generally the result of the first form, a projecting fold left after absorption of the coagulum having undergone further growth. Often there is only a single broad flat excrescence at the side of the anus, but sometimes there are two, one on each side, and occasionally there are several encircling the anus. Similar excrescences occur as the result of irritating discharges from the bowel, and are common in stricture and chronic ulceration of the rectum.

Internal Hæmorrhoids.—Internal piles seldom attract attention until they have become so developed as to protrude at the anus in defæcation. They then exhibit a remarkable diversity of appearance, according to their number, size, and condition. The protrusion may consist of only one large pile, found usually towards the perineum, especially in women. More commonly there are three distinct prominent growths, differing in size, one at each side of the anus, and a third in front—the latter, the perineal, being the largest. In old cases they may be more numerous—as many as four or five. The distinction between them is commonly well marked, but not always, for the piles sometimes merge into each other, so that the protrusion forms nearly a

obscure prominence. The aspect of extruded piles depends much upon their condition, whether congested, inflamed, or constricted by the sphincter. In an inactive state, and in a relaxed condition of the sphincter, they form softish tumours of a granular appearance, presenting just at the orifice of the anus; but when protruded and congested, they constitute large tense tumid swellings, of a deep red colour and smooth surface, which readily bleed. When hæmorrhoids are of large size, the integuments at the margin of the anus become everted, and form a broad band girding the base of the tumours. The skin thus everted is liable to be mistaken for external piles, and to be excised in operations—an error very likely to be followed by serious contraction of the anus.

ÆTIOLOGY.—Hæmorrhoids are a disease of middle and advanced age. They rarely occur before puberty; and but few persons in after-life altogether escape them. All circumstances which determine blood to the rectum, or which impede its return from the pelvis, tend to produce this disease. There is in many persons a natural predisposition to the complaint, which may be hereditary. But a predisposition is most frequently acquired by sedentary habits, indulgence at table, and excitement of the sexual organs. Hæmorrhoids, though a common disease in both sexes, occur more frequently in males than in females. Few women bear children without becoming in some degree affected by them, but the urinary and genital disorders of the other sex, combined with frolic habits of living, leading to congestion of the liver, are still more fertile sources of piles.

SYMPTOMS.—The symptoms produced both by external and internal piles vary greatly in different subjects, and in different stages of the complaint.

External piles cause a feeling of heat and tingling at the anus. A costive motion is followed by a burning sensation, and the excrescence becomes swollen and tender on pressure, so as to render sitting uneasy. This congested state of the pile may pass off; or it may lead to inflammation accompanied with considerable enlargement of the hæmorrhoid, forming an oval tumour, red, tense, and extremely tender. The inflammation may subside or go on to suppuration. When the matter is discharged, a clot of blood escapes with it, the abscess closes, and the dilated vein is usually obliterated, the pile being reduced to a small flap of integument. External piles rarely give rise to bleeding.

Internal piles, when slight, may exist for years, causing little inconvenience besides slight bleeding after a costive motion; with occasionally a feeling of fulness, heat, and itching just within the anus. If only small, they protrude slightly with the mucous membrane in defæcation, returning afterwards within the sphincter. When of large size, the piles always protrude at stool, and require to be replaced, the patient usually pushing them up with his fingers. In a lax state of the sphincters, and in a loose hypertrophied condition of the mucous membrane from which they spring, hæmorrhoids come down, even when the patient stands or walks about, so as to prove exceedingly troublesome, and to interfere with

his taking walking exercise. In consequence of the irritation from pressure and friction to which the protruding piles are liable, their mucous surface becomes tumid and abraded, and furnishes a free mucous discharge tinged with blood, which soils the linen. They are often so sore that the patient is obliged to keep the recumbent posture, the pressure in sitting causing more or less uneasiness.

Persons subject to piles frequently suffer so inconvenient from them until irritated by an unusually costive motion, or by a smart purgative, or when, under the excitement of wine, the growths become congested and inflamed, and cause spasm of the sphincter muscle. Then they have what is termed an 'attack of piles'—that is to say, they experience a sensation of heat, weight, and fulness just within the rectum, followed by considerable pain at stool, and sometimes irritation about the bladder. These symptoms, which are often attended with febrile disturbance, arise from inflammation and swelling of the piles, which afterwards subside, but seldom without leaving some enlargement of the growths. The formation and increase of piles seem indeed to arise chiefly from a determination of blood to the rectum. This is greatly promoted by stimulating drinks, so that some patients never suffer from the complaint except after indulging in this way. They are then rendered sensible of an afflux of blood by a sense of heat or intolerable itching at the anus.

Strangulation.—When internal piles of some size protrude at the anus and are not returned, they are liable to be constricted and strangulated by the external sphincter. The constricted muscle impedes the return of blood, and occasions inflammatory swelling of the piles, which may become strangulated and mortify. In this way hæmorrhoids of large size have been known to slough off, the patient being relieved of the annoying complaint by a sort of natural process. An occurrence of this kind is attended with a good deal of pain and suffering, but is free from danger. In general, the extremities only of one or two of the larger growths perish, and the patients, though experiencing relief, are by no means cured of the disease.

Hæmorrhage.—One of the most common symptoms of internal hæmorrhoids, indeed that from which the name of the complaint is derived, is hæmorrhage, which occurs when the bowels are evacuated. The bleeding varies greatly in amount. Sometimes the motions are merely tinged with a few drops of blood; in other instances the quantity lost is considerable several ounces being voided at stool. The bleeding may be irregular, occurring only after costive motions, or in certain states of health, or it may take place daily, going on even within the bowel, and producing the usual symptoms of derangement from continued losses of blood, such as blanched complexion, loss of strength, quick small pulse, and even œdema of the feet. The character of the bleeding also varies, being sometimes venous, sometimes arterial. There are persons who are liable to discharges of blood from the hæmorrhoidal veins, either at regular periods, or when, from good living or want of exercise, the habit is fuller than usual. In these cases from three

to six ounces of blood, or even more, pass away at stool, following the evacuation; and the blood which is voided is of a dark colour and evidently venous. Such discharges must not be rashly interfered with. They relieve congestion of the liver and kidneys, help to ward off attacks of gout, and prevent fits of apoplexy; so that in many persons they are rightly regarded as safety-valves. But the bleeding which most commonly occurs from internal piles is undoubtedly arterial, taking place from arteries enlarged by disease. The vessels on the spongy surface of the mucous membrane readily give way when blood is determined to the part in defecation, or when abraded by the passage of hard feces. An artery of some size, exposed by ulceration, continues to pour out blood, weakening the patient and giving rise to the symptoms above described. Sometimes a small artery on the prominent part of a protruded pile may be observed pumping out blood. That hemorrhage of this character is good for the health, is quite a mistaken notion; and it is important that the practitioner should distinguish the bleeding taking place as a consequence of local disease, from that which arises from a constitutional plethora or congestion of the internal organs.

TREATMENT. When piles are small and cause but little inconvenience, the treatment is very simple. Persons with this complaint should take wine in great moderation, if at all, and in most instances they would do well to abstain entirely from stimulating drinks. Many individuals never suffer from piles except after taking a glass of spirits and water, or a few glasses of wine. Such persons should become water-drinkers. Active exercise in the open air should be taken daily, and the patient should avoid sitting too long at the desk, because it is by prolonged sedentary occupation and the neglect of the rules of health that hæmorrhoidal complaints are induced. Chairs with cane seats are to be recommended. The bowels must be carefully regulated, so as to avoid hard and costive motions, as well as frequent action. Irritating the rectum by active and repeated purging is more hurtful even than constipation. On the other hand, when the liver is congested, or its secretions are sluggish, and when the bowels are costive, a mild cathartic, by clearing the intestines, especially the colon, unloads the congested vessels, and relieves the piles. Lenitive electuary, rendered more active when necessary by the addition of tincture of potash, may be taken at bedtime; or the compound liquorice powder of the Prussian pharmacopœia, Carlsbad salts, or the foreign mineral waters—the Pullna the Friedrichshall, or the Hanyudi-János—taken in the morning fasting, answer well with many persons, and ensure a comfortable relief. Half a pint of cold spring water injected into the rectum, in the morning after breakfast, has a very beneficial effect on the hæmorrhoids, by constricting the vessels, and softening the motions before the usual evacuation. The relief afforded by this treatment, combined with care in the mode of living, is often remarkable. Ordinary venous bleeding may be stopped in this way. If necessary, lead water, or an astringent injection, such as a solution of tannic acid or infusion of

rhinany, may be used; or an astringent suppository. When the bleeding is arterial, injections are not so successful, and operative treatment often becomes necessary. When there is a slimy discharge from the surface of an exposed internal pile, benefit may be derived from the daily application of tannic acid, mild citric ointment, or the solid sulphate of copper.

External piles, when large and troublesome and internal piles when of such a size as to protrude at stool and to be subject to inflammation, ulceration, and frequent bleeding, can be removed only by operation. T. B. CUMING.

HÆMOSTATICS (*αἵμα*, blood, and *σταῖς*, stopped).

DEFINITION.—Internal remedies and local applications which arrest hæmorrhage.

ENUMERATION.—The chief hæmostatics are:—The Ligature; Pressure; Rest; Cold; the Actual Caustery; Astringents; and the whole class of Styptic drugs.

ACTIONS AND USES.—When taken in their widest sense, it is evident that hæmostatics must include all the various means which have been devised to stop bleeding. Externally we must vary our plan of treatment according to circumstances. No surgical principles are better founded than those which enjoin us to tie a wounded artery, and to apply pressure to a vein; and for the absolute arrest of hæmorrhage from any readily accessible part a most powerful aid has lately been provided in Eschsch's elastic bandage. When the bleeding depends on general capillary oozing, the application of ice may often prove effectual; and where this fails, recourse must be had to some of the numerous articles of the pharmacopœia, already referred to, which are endowed with styptic properties. (*See STYPTICS*.) An example of the successful application of a hæmostatic is the arrest of uterine hæmorrhage by means of injections of perchloride of iron.

In the case of undue hæmorrhage from a leech-bite, if milder remedies, such as pressure, do not succeed, we may apply the solid nitrate of silver, or include the bleeding point in a loop of twisted suture. Absolute rest is essential for the successful treatment of hæmorrhage; and the regulation of the diet and of the bowels is equally to be attended to. For the details of treatment in each particular form of hæmorrhage, the reader is referred to *HÆMATINURIA*, *HÆMOFILIA*, *HÆMOPTYSIS*, *MELENA*, &c.

ROBERT FARGUEHARSON.

HÆMOTHORAX. *See* *HÆMATO-THORAX*.

HAIR, Diseases of.—Alterations of the hair from the normal and healthy standard may be comprised under three heads—*quantity*, *quality*, and *direction*.

Alterations in quantity.—As regards quantity of the hair, there may be either *excess* or *diminution*.

Excess of hair.—Excess may be the consequence of multiple development from the follicles, leading to the production of a greater number of hairs than usual; or it may result from excessive growth, which brings into view the usually invisible hairs of the body, more or less generally.

or partially. Of the latter kind are the hairy men and women of whom so many instances are recorded; and the abnormal growth of hair on parts of the body where its presence is normally but little perceptible, for example, on the face of women, in the form of moustache whisker, or beard. The hair of the head, as well as that of the beard, sometimes attains an excessive length. Moreover, hair may be abnormal in situation as well as in growth, as seen in the varied examples of pilous nevi.

Diminution of hair.—Diminution may present itself as shortness in length from slowness of growth, or numerical deficiency from arrest of growth; and the latter may proceed onwards to baldness more or less complete. See BALDNESS.

Alterations in quality.—Alterations of quality of the hair are manifested by variations in its physical conditions, alterations of colour, and pathological changes of structure.

Physical conditions.—The hair, normally smooth, lustrous, soft, and elastic, may become rough, dull, harsh and rigid, or brittle.

Colour.—Alteration in colour of the hair usually ranges between the lighter tints of childhood and the darker hues of the adult, and the arrest of pigmentation which gives rise to the greyness of every period of life and the hoariness of old age. Absence of pigment, complete or partial, is sometimes congenital. Alterations of the colour of the hair occasionally take place during the course of a serious illness; or the hair may become blanched in the space of a few hours from mental disturbance. There is another aberration of colour of the hair, which consists of an alternation of brown and white in narrow segments, extending from end to end of the hair—a kind of 'ringed' or 'banded' hair. A few examples of this peculiar change in the hair have been preserved and recorded.

Structure.—Alterations in structure of the hair are shown by its atrophy or attenuation; by its defective consolidation; by a pathological alteration of its elementary constituents, and by the morbid changes induced by syphilis. It is not uncommon to find the hair dwindled to a mere vestige of its original bulk, and, when this takes place, it is apt to break off near the point of attenuation, and present the appearance of a club-shaped stump. Broken hairs of this character, with filamentary pedicles, are found at the circumference of a spot of alopecia areata. Or the hairs may be fragile in texture, and break partially through at short distances, so as to give a speckled appearance to the hair-shaft. This change is generally met with in the thick hairs of the whiskers and beard, and is termed *trichodalia* or *fragilitas crinium*. In these the formative cells of the hair retain their elementary fetal form, or proliferate in the substance of its shaft, rendering it brittle and causing its destruction; the cell-proliferation constituting the trichophyton among the parasitic fungi. In syphilis, the hairs of the whiskers and beard have been found swollen, as though varicose, and discoloured from imperfect cell-development.

Alterations in direction.—Altered direction of the hair is met with on the edges of the eyelids, where the hair may grow inwards and

press against the corner, so as to give rise to conjunctivitis; this form of affection being termed *trichiasis*. The matting or felting of the hair in *placa polonica* may likewise be ascribed to misdirection, though in a different sense, namely, as resulting from neglect.

Ætiology and Pathology.—Numerical quantity of hair can be considered pathological only when that quantity interferes by its excess with the comfort and convenience of the individual. This can rarely occur when the hair is produced in normal situations, and grows to excessive length, the remedy being obvious. But when it is developed on the face of the female in the form of moustache, whiskers, or beard, it is then an annoyance very nearly approaching to that of a disease. This is still further increased when the greater part of the body becomes invested, as sometimes occurs, with a thick, hairy covering. An excess of pilous growth is, in general, a mere augmentation of a natural function; occasionally, it appears to be the result of a substitutive function, as in sterile females, or when the procreative power is exhausted through age, and at other times, as in pilous nevi, it is due to abnormal organisation of the affected skin.

Diminution of quantity of hair, and arrest of pilous growth, must in every instance be due to aberration of nutrition, and atrophy of the formative papillæ of the hair. This may be the consequence of debility, however induced, whether by age or disease. Very commonly the hair breaks away from the papilla without undergoing any previous alteration of figure. At other times it becomes attenuated and starved before it eventually drops off. Sometimes the nutritive power is simply suspended; while at other times it is completely arrested, temporarily or permanently, and gradually or on a sudden. After serious illness the hair is apt to fall off, not unfrequently thus occurs after puerperal confinement; dropping off of the hair is known to be a frequent concomitant of syphilis; and it presents the characteristics of a nerve-lesion in *alopecia areata*. In cases of universal baldness the skin is soft, pulpy, and feeble, deficient in colour as well as in firmness and tone, and smooth from the absence of papillæ.

Alteration of colour of the hair is generally attributable to variations in quantity, and modification of pigment. But in cases of sudden blanching of the hair, the apparent whiteness has been found to depend on the rapid development of a gaseous fluid within the substance of the hair, obscuring the pigmentary granules to which its colour is due. This has likewise been observed to be the case in the instance of ringed or banded hair.

Alterations of structure of the hair are for the most part due to modifications of development and growth of its constituent cells. The elementary cells may be produced in greater or less quantity, changing the bulk of the hair; they may be more or less abundantly and completely converted into hair-fibre; they may retain permanently their undeveloped or cell-character; or they may become the subject of an abnormal proliferation within the shaft of the hair. As the firmness, elasticity, and pliancy of the hair are due to the perfection of its development, so the

opposite qualities are referable to abnormal development. The shaft of the hair often varies in its diameter; the medullary space equally varies; it may be fractured completely, as in ringworm; or partially, and with slight force, as in *trichoclasis*. The hair of ringworm is made up of round cells and proliferating cells, with a deficiency of fibrous structure, hence it dries and shrivels up as though withered, or breaks off close to the head, leaving behind short stumps. When syphilis attacks the hair, its structure is likewise rendered brittle.

TREATMENT.—The therapeutic treatment of the diseases of the hair may be summed up very briefly. Where the hair is in excess it must be removed; where it is deficient it must, if possible, be restored; and where its structure is altered, it must be repaired by renovating the health of its formative organ, the skin.

Contrivances for removing the hair are termed depilatories, they act for the most part by destroying and dissolving the hair. Their application requires caution, on account of their irritant qualities, and they are open to the objection of being merely temporary in their effects. The only trustworthy depilatory is the razor. See **DEPILATORIES**.

For defect of growth in length, as also in quantity, we must have recourse to tonic or stimulant remedies. Tonics, such as arsenic, quinine, and iron, improve the nutritive power of the skin; and stimulants for external application arouse the energies of the tissues of the skin, more especially those of the blood vessels and nerves. The usual stimulants adopted for this purpose are ammonia, cantharides, mustard, the various stimulating liniments, and acetic acid. See **BALDNESS**.

For the purposes of fashion or convenience, the colour of the hair may be discharged by solutions of oxygen, notably the peroxide of hydrogen; and also by alkalis, with more or less injury to the hair. It may be restored artificially by the various hair-dyes, which are either temporary or permanent. Of the former kind are the permanganate of potash, and the black oxide of lead, and of the latter the black oxide of silver.

Alterations of structure of the hair due to debility of the skin require the aid of constitutional tonics and local stimulants. Where ringworm is the cause of the morbid change of the hair, there is a chronic inflammation to be subdued, as well as a feebleness of nutritive power to be repaired. In the fall of the hair from syphilis, the specific remedies for that disease are required.

Alteration of direction of the hair may be corrected by avulsion with the forceps; and the setting of the hair in plica polonica may be prevented by ordinary care and attention.

EMANUEL WILSON.

• **HALL**, in Austria. Common salt waters. See **MINEERAL WATERS**.

HALLUCINATION (*hallucinator*, I blunder).—A false perception of an organ of sense, for which there is no external cause or origin (see **ILLUSION**); as when a man in total darkness thinks he sees an object. Hallucinations of all

the senses occur, the most frequent being those of sight and hearing. They may be found in persons not insane, but indicate a disordered state of brain.

HANGING, Death by.—Hanging is the effect of suspension of the body by the neck by means of a ligature or noose, the constricting force being the weight of the body, wholly or in part, or the weight multiplied by the distance through which the body falls. The mode of death varies according to these circumstances. With a long drop, the method now usually employed in judicial hanging, and particularly if the knot is under the chin, death is not unfrequently due to fracture, or displacement, of the cervical vertebrae, and injury to the medulla oblongata. Death may also occur, without such anatomical lesion of the cervical vertebrae, from shock or syncope, or, as it is termed by Casper, *neuro-paralysis*.

When death does not occur in either of these ways, it is the result of asphyxia from occlusion of the air-passages, or rather of asphyxia in combination with coma, caused by compression of the cerebral blood-vessels. Though compression of the carotids and jugulars may be maintained for a considerable time without a fatal result, if the trachea is open below the point of constriction, where death speedily ensues if the air-passages are also occluded, yet death may result from the disturbance of the cerebral circulation alone, and the two causes always operate conjointly in every case, in varying proportions.

PHENOMENA.—When death is not instantaneous, as in cases of injury to the medulla, or from *neuro-paralysis*, convulsive movements of the type seen in asphyxia may continue for some minutes after suspension, and the heart may continue to beat for a considerable period after all other vital movements have ceased.

Subjects who have been partially hanged have described various sensations, more or less pleasurable, similar to those of cerebral congestion and narcotic stupor.

POST-MORTEM APPEARANCES.—The appearances found after death by hanging are not uniform or constant, and there is no single sign invariably present diagnostic of death by hanging. Indicative of suspension, but not necessarily of death so caused, is the mark of the cord on the neck. Usually it is above the hyoid, passing obliquely upwards behind the ears, and losing itself in the occiput. But the position may vary according to the tightness of the noose before suspension, or the position of the head and direction of the pressure. It is generally single, but if the cord should have been twisted twice round the neck, two marks may be found, one circular and the other oblique. The characters of the mark differ somewhat according to the texture and thickness of the ligature. Usually it is a shallow groove or furrow of a whitish or brownish hue and parchmenty consistence, occasionally abraded, rarely ecchymosed; but it may have livid edges or a chocolate tint. The appearances may vary in different parts of the same mark. The subcutaneous cellular tissue is compressed and silvery. Occasionally minute extravasations are seen in the deeper layers of the skin. The

middle and internal coats of the carotids are sometimes lacerated; and where the momentum has been great, lacerations of the cervical muscles, fracture of the larynx, rupture of the thyro-hyoid ligaments, and fracture or dislocation of the cervical vertebrae, with injury to the medulla and entrance into the spinal canal, have been found. All the appearances usually found in the neck in cases of hanging may be produced by suspension of the dead body, especially if the legs are pulled forcibly downward.

The face is sometimes, but not commonly, distorted and expressive of suffering. Usually it is placid and pale, though if the body have hung for some time, it becomes very livid. The eyes are sometimes very prominent, and the pupils are usually dilated. Frothy mucus may be found at the mouth and nostrils. The tongue is pressed against the teeth and indented, or it may be clenched between the jaws. The base of the tongue is injected. The hands are often tightly clenched, the nails even being driven into the palms. Erection, or semi-erection, of the penis in men, with expulsion of semen or prostatic fluid, and vascular turgescence of the genitals in females, with sanguinolent effusion, are frequently observed. Expulsion of the contents of the bladder and rectum is likewise common. The condition of the brain varies. Congestion is sometimes pronounced, at other times not very marked. The mucous membrane of the larynx and trachea is congested, and mucous froth is present. The lungs are at times pale and distended, at other times collapsed. The condition of the heart and venous system characteristic of asphyxia is common. Marked redness of the mucous membrane of the stomach, simulating irritant poisoning, has been occasionally noted. The determination of the fact of death by hanging depends on a consideration of these various phenomena, and the absence of other causes of death.

ACCIDENT, SUICIDE, OR HOMICIDE?—Hanging is rarely homicidal. It signifies great disproportion of strength between the assailant and the victim; and, therefore, in the absence of this condition, there will be injuries indicative of a struggle. Apart from collateral circumstances, homicide can only be argued from the presence of such injuries as could not have been self-inflicted, or caused accidentally during the act of suspension. Occasionally hanging is accidental, as in foolish experiments and insane imitation. It is not necessary that the body should be entirely off the ground to cause death by hanging. Many instances are recorded of suicide by hanging in most extraordinary positions calculated to throw the greater part of the body-weight on the noose.

TREATMENT.—This is rarely called for, except in accidents or attempted suicide. The body must be cut down, and artificial respiration employed. Venesection may be had recourse to for relieving cerebral congestion. See **ARTIFICIAL RESPIRATION**; and **REANIMATION**. D. FERRIS.

perature, 39° Fahr. Exposed to the east, but sheltered from the north. See **CLIMATE**, Treatment of Disease by.

HAUT MAL (Fr.)—A synonym for epilepsy gravior. See **EPILEPSY**.

HAY FEVER.—**SYNON.** *Catarrhus entosis*; Bostock's catarrh; Hay asthma; Fr. *Asthme d'été*; Ger. *Frühommercatarrh*.

DEFINITION.—A catarrhal affection of the mucous membrane of the eyes, nose, mouth, pharynx, larynx, and bronchi, accompanied by dyspnoea; induced by the action of the pollen of various plants chiefly of the graminaceae; prevalent during the hay season, but subsiding at its close, and varying in severity according to certain atmospheric conditions, and the amount of pollen present in the air.

ETIOLOGY.—Hay fever exists in Europe generally, but it is by far most common in England, where the annual number of cases is double that of any other country. It prevails more among men than women, probably because the former are most exposed to the atmosphere; and inhabitants of towns visiting the country are more liable to attack than the country people themselves. It has been ascribed by some writers to the sun's heat in the summer months, also to certain odours vegetable and animal; but the experiments of Mr. C. H. Blackley show it to be due to the specific influence on certain mucous membranes of the pollen grains of the following natural orders of plants:—Ranunculaceae, Papaveraceae, Fumariaceae, Cruciferae, Violaceae, Caryophyllaceae, Geraniaceae, Leguminosae, Umbelliferae, Rosaceae, Liliaceae, Compositae, Gramineae, and others, both exotic and native. Pollen was applied to the mucous membrane of the (1) nares, (2) larynx, trachea, bronchial tubes (by inhalation), (3) conjunctivae, (4) tongue, lips, and fauces, and in all these cases it produced the symptoms of hay fever, the pollen of grasses being most potent. Amongst these seeds cereals, or rye, exercised most marked effects, though greater influence is generally attributed to *anthoxanthum odoratum*.

It has been found that large quantities of pollen float in the air during the summer months; and that the number of cases of hay fever depends on the amount present, which increases in warm damp weather, decreases when it is very dry and hot, and often nearly disappears after heavy rain. Cold weather reduces the number of sufferers by checking the inflorescence of plants. The higher strata of the atmosphere appear to contain more than that immediately overlying the soil, and Mr. Blackley found the greatest number of pollen-particles at between 1,000 and 1,500 feet above the earth's surface, whither they are probably carried by aerial currents. The number of pollen-grains present reaches its maximum in June, when Mr. Blackley collected 880 in a day on a square centimetre of glass. The size and forms of the pollen-grains vary greatly in the different species, but this does not seem to influence their action, which appears to depend on the pollen-grain absorbing moisture from the contiguous mucous membrane and bursting, when the minute granules it contains are thus extruded, and cause irritation.

SYMPTOMS.—An attack of hay fever generally occurs without any premonitory disturbance, immediately on the application of the pollen to the mucous surfaces, for instance, when the person enters a hay-field. The first symptoms are itching of the parts with which the particles come in contact, beginning with the hard palate and fauces, and then extending to the nostrils, the eyes, and face, though, if the wind be strong, the eyes may be first attacked. The catarrhal stage follows, marked by violent fits of sneezing, and running from the eyes and nose, with occasional pains in the head and in the frontal sinuses; then the sub-mucous tissue of the nares swells, and in a short time both nostrils become blocked and impervious to air. A change to the recumbent position, however, if the patient lies on one side, will often reopen the uppermost nostril, while the other, from the force of gravity, becomes still more occluded. The sneezing will continue without fresh application of pollen, as at night, when the subsidence of the swelling restores, or even exaggerates, the sensibility of the Schneiderian membrane. The *nasæ* nasi become red and inflamed, and occasionally bleed. The discharge after this becomes less in quantity, inspissated and puriform, and finally subsides. In the eyes, the swelling of the submucous tissue causes closure of the lachrymal canals and nasal ducts, and considerable injection of the conjunctival capillaries is apparent. Sometimes, but rarely, oedema of the eyelids follows. Similar to the nose-symptoms are those occurring in the throat, some swelling taking place in the pharynx, which gives rise to partial closure of the Eustachian tubes, and hence to a certain degree of deafness. Slight feverishness is occasionally present, the pulse quickening to 100, and the temperature slightly rising, but in a large number of cases pyrexia is entirely absent. The changes which take place in the mucous membrane of the air-passages give rise to asthmatic symptoms, such as tightness of the chest, difficult and wheezy breathing, with prolonged expiration, and some dry cough, followed, at the close of the attack, by expectoration.

The catarrhal symptoms are, however, more characteristic than the asthmatic, which are not invariably present.

The liability to attack lasts generally from three or four weeks in summer, but its duration depends on the presence of the exciting cause, which, if not removed, may cause the malady to last for months. A fall of rain will diminish the disorder by clearing the air of pollen, exercise, which increases the number of respirations and, therefore, of pollen-grains inspired, will render it more severe; while each attack makes the individual more susceptible to this subtle influence, and, consequently, augments the probability of other seizures. As a rule, hay fever has no complications, and passes away completely on the removal of the exciting cause. Constant recurrence of the attacks has been noticed to lead to deafness, owing to catarrh of the Eustachian tubes.

DIAGNOSIS.—The diagnosis of hay fever from other affections is easy, as the occurrence of the catarrhal symptoms only in summer separates it from an ordinary 'cold in the head', while their

combination with dyspnoea in hay fever prevents its being mistaken for spasmodic asthma arising from other causes, in which there is usually no catarrh.

PROGNOSIS.—The prognosis is favourable if the patient be removed from the exciting cause, as the asthmatic symptoms seldom, if ever, lead to pulmonary emphysema, or to any permanent change in the bronchi.

TREATMENT.—The most obvious course in the treatment of hay-fever, but not always the most easy one, is to avoid exposure to pollen. Mr. Blackley notices that a small amount of this material might exist without giving rise to hay fever, but if ten grains of pollen were detected on the glass slide exposed to the air for twenty-four hours, symptoms were sure to appear in persons liable to it. Sufferers from this complaint should avoid hay-fields, hay-ricks, and much exposure and exertion in the country during the hay season, and should remain to a great extent within doors; but where circumstances admit, change to the seaside is highly desirable, and it generally effects a speedy cure. Even on the coast some care must be taken to select a locality free from vegetation; for if the wind blows from the land, where hay-grass be flowering at the time, an attack may be induced. Choice should be made of a seaside place backed with high cliffs, and where the prevailing winds are from the sea. Of other localities, high mountain stations, where there is more grazing than hay-growing, and closely inhabited cities with few parks or grassy squares, are to be preferred. Cotton-wool and other respirators available are sometimes used with advantage.

The medicinal treatment consists in first combating the general predisposition to the complaint by tonic measures; and, secondly, in allaying the local irritation.

The first object is best achieved by shower baths, and by such tonics as iron, quinine, sassafras, sulphate of zinc, and arsenic. Lotions of sub-acetate of lead or sulphate of zinc applied to the eyes and inner surface of the nostrils give some relief, but the writer has found the most successful results from the use of the spray-apparatus, containing solutions of carbolic acid (eight grains to an ounce), sulphurous acid (equal parts with water), sulphate of quinine (two grains with acid to an ounce), and tannic acid (four grains to an ounce). The spray may be applied to all the irritated surfaces—eyes, nose, throat, and larynx—with great relief. C. THOMSON WILLIAMS.

HEADACHE.—**SYNON.**: Cephalalgia; Fr. *Douleur de tête*, Ger. *Kopfschmerz*.—Pain or uneasiness in the head is very variable in its nature, and produced by a great number of causes. It is present at some period or other in the course of most acute, and many chronic diseases; and may be associated or not with organic change in the brain, or in other organs of the body.

SYMPTOMS.—Headache presents many varieties. It may be slight or most intense; superficial or deep-seated. It may be more or less confined to particular parts, as the forehead, the temples, the occiput, or vertex. Sometimes the pain is limited to one spot, producing the sensation as if a nail were being driven into the head, when it is called *clavus*. It may extend over one side of the head,

as in *hemiparesis* or *migrain*; or be generally *diffuse*. Headache presents every variety of *character*—dull, sharp, cutting, &c. Its *accession* may be sudden or gradual; and the *paroxysms* may be of the shortest possible duration, or may extend over hours, days, or months. The pain may be simple, or associated with various *perverted sensations*, such as giddiness, tingling in the limbs, disordered hearing, or disturbances of vision.

VALENTIN.—For practical purposes headaches may be arranged in the following order:—

1. *Structural headache*, or headache dependent upon disease within the cranium.

2. *Congestive headache*.

3. *Nervous or sick headache*—*hemiparesis* or *migrain*.

4. *Toxic headache*.

1. *Structural headache*. This may be due to any of the many forms of disease of the brain, or of its membranes, such as meningitis, cerebral softening, abscess of the brain, cerebral tumour, &c.; or it may be premonitory of cerebral softening. It is nevertheless often wanting in these disorders, and the locality of the pain, when present, by no means corresponds with that of the lesion. As a rule the pain of organic disease is fixed and habitual, though sometimes, as in abscess or cancerous tumour, it may be of an intermittent character. If there be sickness associated with it, the sickness occurs without any apparent gastric disorder, and the pain continues after the sickness ceases. Stooping and even the recumbent posture aggravate the pain, whilst it is lessened by elevating the head. If organic disease be suspected, the collateral symptoms must be carefully scrutinized and weighed. It rarely happens that organic disease needs to be inferred from pain alone.

2. *Congestive headache*. Many forms of headache depend upon a greater or less degree of congestion of the vessels of the brain, the congestion being either active or passive.

Active congestion may be caused by hypertrophy of the left ventricle of the heart, general plethora, catamenial irregularities, mental or emotional excitement, and other conditions. The pain in such cases is of an obtuse character, affecting the whole or a part of the head, particularly the forehead and occiput. It is accompanied with a sense of pulsation in the ears, flushed face, glittering eyes, and giddiness on stooping.

Passive congestion may be produced by dyspnea, by asthma, by valvular defects in the heart, or by defective action of the liver, bowels, and skin; it may be the after-effect of drunkenness; or may result from any cause which can produce a state of debility in the vessels of the brain, such as general anemia, exhaustion from fatigue, loss of blood, leucorrhoea, or that following over-excitement, mental exertion, or bodily fatigue—causes which all favour congestion. When the headache is induced by anemia or debility, the pain is most generally across the forehead or at the top of the head.

3. *Nervous or sick headache, hemiparesis or migrain*. This disorder is discussed in a separate article. See *MIGRAINE*.

4. *Toxic headache*. The headache which

attends all fevers and inflammatory disorders, though due in some measure to cerebral congestion, is chiefly caused by the action of the blood, altered in character and elevated in temperature, on the nervous elements of the brain. In uremia likewise the headache which frequently precedes or accompanies the other symptoms pointing to the existence of renal disease, results from the morbid condition of the blood. So also in some persons, breathing the impure air of a crowded room, or the products of the combustion of gas, will, by the imperfect decarbonisation of the blood, speedily produce a headache.

Besides the above varieties of headache, pain about the head external to the brain may be produced by *rheumatic* affections of the scalp, with tenderness of the skin and rheumatism in other parts, by *sypilitic* affections of the periosteum or bone, by *inflammation* of the scalp, commencing *crispella*, &c., and by trigeminal and other varieties of *neuralgia*. From neuralgia headache may be discriminated by its mode of accession; by the generally longer duration of the attack; and by the more complete intermissions.

TREATMENT—The treatment of headache must necessarily depend upon the peculiarities of each individual case. In organic or toxic headache the disease with which it is associated, and not the symptom itself, will of course be the object of consideration, and the treatment will be found discussed in connection with these special morbid states. The same remark applies to many forms of congestive headache, such as those produced by disease of the heart, asthma, &c. If catamenial irregularities or uterine disorders are the exciting cause, these must be treated by appropriate measures. If anemia or debility be present, then in the intervals between the paroxysms, iron in some form, either alone or in combination with quinine or some vegetable bitter, must be given. During the paroxysms a little sal volatile, a cup of soup or strong tea or coffee, or some weak alcoholic stimulant may be of service. Where anemia is not a prominent symptom, or when the disorder assumes a periodical or intermittent character, quinine alone, in doses of two or three grains twice or three times a day, may be given, and if this fails to afford relief, arsenic is often of signal service. Great benefit is frequently afforded in the latter cases by the administration during the paroxysm of alcohol. Except when the headache is associated with general plethora or active congestion, strong purgatives are to be avoided, and the bowels are to be regulated by the mildest aperient which will answer the purpose. The patient's habits and mode of life must also be strictly regulated; and care must be enjoined as to diet, sleep, clothing, and exercise, especially if the headache be associated with dyspepsia. If dyspeptic symptoms are prominent, or if the pain be connected with a gastric diathesis, then these disorders must be treated with their appropriate remedies.

If during the paroxysms the head be hot and the face flushed, warm or cold lotions, iced water, or eau-de-Cologne may be applied; a warm douching may be useful in some cases. Occasionally in severe attacks a few leeches may be placed on the temples with advantage, or a blister to the nape of the neck, but never if the face be

pale, and the pulse feeble. Compression of the temporal arteries with a pad, sustained pressure around the head, or holding the arms high above the head, will sometimes relieve severe headache.

The treatment of neck-headache is discussed under the article *MIGRAINE*. P. W. LATHAM

HEALTH, Maintenance of. *See* *DISEASE, Causes of; PERSONAL HEALTH; and PUBLIC HEALTH.*

HEARING, Disorders of.—These disorders may be grouped under three classes, namely:—(a) *Partial or complete loss of hearing or deafness*, (b) *Exalted hearing* (so-called), (c) *Perverted hearing or Tinnitus*. They may be due to various conditions quite independent of any actual disease of the auditory apparatus, and only such causes of disordered hearing will be considered in the present article as are not due to changes in the conducting portion of the ear, which can be demonstrated by the different methods of examination, or to recognised affections of the nervous apparatus connected with hearing. These will be found discussed under the article *EAR, Diseases of*.

(a) *Partial or complete loss of hearing*.—Perhaps the deafness due to accumulations of cerumen, which so frequently interfere for a time with the hearing of persons whose ears are free from disease, should be regarded as disordered hearing, rather than as a symptom of a pathological condition. As nothing more energetic than careful syringing is required to remove such obstructions, it will be sufficient to observe that in this proceeding the nozzle of the syringe should be directed along the roof of the external canal. Amongst a very large number of people with the organs of hearing in an apparently healthy state, some few will be found upon whom, throughout their lives, certain notes produce no response. They will not, for example, be able to hear the sounds made by grasshoppers, or the singing of some birds—the call of a partridge, for instance; and in most persons, as age advances, the very high notes are lost. To prove this, it is only necessary to blow one of Mr Galton's whistles in a room full of people, when a considerable proportion of the assembly will fail to catch the high notes, which are distinctly heard by the rest, and although this failure is also noticeable in many nervous affections, all other sounds will perhaps be heard quite normally by these individuals. Emotional influences play a very large part in the destruction or suspension of hearing, and this is especially observable in the case of women. The unexpected sight of a dead husband, hearing of the death of a dear friend, the proposal of a severe surgical operation on a relative, a quarrel, an alarm of thieves, and witnessing a carriage accident, have each within the knowledge of the writer been followed by intense and sudden deafness, which has only been partially recovered from. The same effect has been noticed with men who have been subjected to prolonged mental strain, in connection with literary work, or during commercial crises. It has been recorded that a deaf and dumb child has suddenly recovered hearing, after the discharge from the bowels of eighty-seven lumbrici, and a large number of oxyurides (*Journal of Med. Society*, 1844). Complete loss of hearing,

extending over several months, was on one occasion followed by perfect hearing in a girl of fifteen, on the first appearance of menstruation. The temporary effect of quinine and salicylic acid on the hearing is well known, but when quinine has been administered in large doses, and for a long period, this special sense is not unusually injured permanently. Amongst the diseases which often induce a lasting deafness, without any perceptible local change in the conducting portion of the ear, may be included mumps, many of the fevers, and diphtheria; for although in the two latter examples the middle ear often suffers, this is not always the case, and the immediate cause of the deafness must be sought in the products of inflammation which have been left within the cranium. The same explanation is probably also the correct one in those instances where children lose for ever all hearing power, after cerebral excitement or congestion. Habitual and obstinate constipation is sometimes attended with loss of hearing, which returns after the action of purgative medicine. A clot of blood within the cranium, whilst causing hemiplegia of the opposite side, may destroy the hearing of the same side as the effusion, and a case is on record in which closure of the cerebro-spinal foramen gave rise to this symptom.

(b) *Exalted hearing*.—What is termed *exalted hearing* will generally, on careful examination be found to be not so much a definite change in the capacity of the hearing apparatus to receive impressions, as an inability on the part of the patient to receive such impressions without an undue effect on the nervous centres being produced. Thus in many inflammatory states of the brain or its membranes this symptom is often a prominent one. It is also not uncommonly met with in hysterical and nervous persons.

(c) *Perverted hearing*.—Attendant on most of the above examples, and closely allied to deafness, is the often persistent tinnitus; but there are conditions in which this distressing symptom is the chief and solitary trouble. Thus tinnitus, with a feeling of pulsation in the ear, is occasionally the first warning of an intracranial aneurism; whilst a furious tinnitus and the hearing of strange noises sometimes precede an attack of acute mania. Patients who have been the subjects of malarial fevers and sunstroke often complain of tinnitus; and, as in all cases of disease of the ears, when present it is the most intractable of symptoms, so it is when the ears have not been the seat of any malady or injury.

TREATMENT.—Inasmuch as all the above states of disordered hearing may strictly be said to be due to causes which are in themselves abnormalities of one part or another of the organism, it is to these that the treatment will naturally be directed rather than to alterations in hearing which in truth are merely symptoms. *See* *EAR, Diseases of*; and *TINNITUS*. W. B. DALRY.

HEART, Diseases of.—The study of this class of diseases has reference to the immediate pathological changes which occur in the heart itself, and to the consequences or results of these changes upon its function, that is to say, upon the circulation of the blood. The latest

portion of the subject will be found discussed under the head *Circulation, Diseases of Organs of*; and it will therefore be necessary in this place to summarise only the morbid changes which affect the heart itself, and this merely as an introduction to the full description of those changes contained in the articles which follow here, or which will be found in other parts of this work.

1. The heart may be *displaced, misplaced, or misformed*. 2. Its various textures, including the coverings, the lining membrane, the valves, and the walls, are liable to *acute and chronic inflammation* and their effects. 3. The organ itself may be increased in size, either by general *dilatation* of one or of more of its cavities, or partially, as by *aneurism* of the walls; or by the addition to its volume, by *hypertrophy* of its muscular structure, of the *fatty* tissue which exists beneath the pericardium, or of the *connective tissues* which binds the muscular fibres together. 4. Its volume may be diminished by simple or general *atrophy*; or by the walls of one or more of its cavities being *wasted and thinned*. 5. Its walls are liable to various forms of *degeneration*—more especially *fatty, granular, calcareous, and pigmentary*. 6. They may be the seat of *fibroid disease*; and of various *morbid growths*, such as *cancer, tubercle, and syphilitic formations, or hydatids*. 7. *Conception and hemorrhage* may occur in the walls of the heart. 8. These are liable also to such injury as *rupture*—whether spontaneous or as the result of violence; and to various kinds of *wounds* and their effects. 9. And lastly, the reader will find discussed under the head of *functional disorders* of the heart, certain disturbances in its action and sensibility which cannot be clearly referred to any structural lesion.

HEART, Abscess of. See **HEART, Inflammation of**; and **HEART, Pyemic Abscess of**.

HEART, Aneurism of.—**DEFINITION.**—A depression or a sacculus formed in the walls of the heart, communicating with one or more of its cavities.

The term aneurism of the heart has not been always used in this sense. It was first applied by Lancini and subsequently by Bouilleau to every dilatation of the heart, whatever its cause or its character. The first case of the disease, as the term is now understood, was published by Galeotti in 1787. In this country, Dr. Thurnam, Dr. Pencock, and others have treated the subject fully. In France aneurism of the heart has been described specially by Brechet and by Pelvet; whilst in Germany, Lohstein, Löbl, and Hartmann have written upon it at length. A full account of the remarks of these and several other writers will be found in the work of M. Pelvet—*Des Aneurismes du Cœur*, Paris, 1867.

ÆTIOLOGY AND PATHOLOGY.—The essential condition which leads to aneurism of the heart is a change in a portion of the heart's texture, by which the resisting power of the affected part against the pressure of the blood from within the cavity is diminished. Under such circumstances a simple depression, corresponding to the weakened spot, may be first formed on the inner surface of the heart. This gradually continues through the cardiac wall towards the external surface, where

the resistance becomes less, and where a pouch or sac is then formed, communicating with the cavity of the heart, it may be by a neck. The weakened condition referred to is attributable in different instances to inflammation of the substance of the heart, whether acute or chronic; to syphilitic or other growths; and to fatty degeneration.

(a) *Inflammation* of the heart, affecting either the endocardium or the substance of the heart itself, may lead to ulceration and softening; and both conditions have been found in connection with aneurism. Inflammation may also lead to the formation of pus in the walls of the heart; and cases are recorded in which, the contents of the sac thus formed having been discharged into the circulation, the cavity became converted into an aneurismal pouch (Dr. Wilks, *Path. Soc. Trans.*, vol. xii.). Cases of aneurism of this character may be regarded as originating in *acute inflammation* of the heart.

In a still larger number of cases, in which the endocardium and pericardium, as well as the muscular walls, are involved, we find a development of fibroid tissue—a *cirrhosis*, as it were, of the heart, as the result of *chronic inflammatory action*. In these cases the fibroid tissue is stretched at each systole of the heart, and it returns less and less to its former dimensions, owing to its want of elasticity. Thus by degrees the portion of the heart affected yields and is pushed outwards, forming a sac of a more or less globular shape.

(b) *Growth* in the heart, whether syphilitic, or tuberculous, undergoing the process of softening, may lead to the formation of aneurism, as in the conditions just described.

(c) *Fatty degeneration* may give rise to the formation of aneurism. First, a circumscribed spot of softened tissue in the wall of the heart, the result of fatty degeneration, yields without rupture, to the pressure of the blood from within, and thus allows of the formation of an aneurismal pouch. Secondly, partial rupture may take place in the muscular wall, and hemorrhage occurring at this point, constitutes what is called 'cardiac apoplexy' (see **HEART, Hemorrhage into the Walls of**). The clot thus formed undergoes the changes usual in extravasated blood, and a cyst results, which may ultimately communicate with one of the cavities of the heart. Merfede Lucenne, who wrote on aneurisms of the heart, believed that this form of disease was almost exclusively thus developed.

With reference to the relative frequency of the various causes of cardiac aneurism, just enumerated, the writer finds that out of a total of 56 cases, the histories of which were collected by himself, in 21 the walls had undergone fibroid changes; in 6 there was fatty degeneration; in 3 the disease was the result of ulceration; in 2 cases it appeared to have originated in alacæa, and in 34 the materials were not sufficient for arriving at an accurate conclusion.

Age.—With regard to the age at which this disease occurs, in 51 of the 56 cases just alluded to the oldest was eighty-two, the youngest a child of twelve. Two cases occurred between ten and twenty years of age, 9 between twenty and thirty, 8 between thirty and forty, 7 be-

tween forty and fifty, 7 between fifty and sixty, 10 between sixty and seventy, 6 between seventy and eighty, and 2 between eighty and ninety years of age.

Ser.—Of the 56 cases, 30 were males and 17 females.

ANATOMICAL CHARACTERS.—Keeping in view the several conditions just described, under which aneurism of the heart can occur, we may expect to find a corresponding variety of morbid appearances. On laying open the pericardium in cases in which aneurism of the heart exists, adhesions which are more or less universal or which may be limited to the seat of the disease, are very frequently found. The heart itself is generally enlarged; and where the aneurism projects externally it is altered in shape, so much so in some instances that the organ looks like a double heart. The sac may project from the walls as a rounded or conical tumour; or, as in an instance that came under the notice of the writer, it may assume the appearance of an elongated sac winding round the base of the aorta. Again, no appearance of anything abnormal may be observed until the heart is laid open, when a depression or an opening may be discovered in the walls of the ventricle, or in the septum. In some instances more than one pouch is formed, in communication with the cavity of the heart by a separate or by a common opening. The size of the tumour may vary from that of a small bean to that of an average-sized cocoa-nut. The opening leading into the pouch may be the widest part of the sac, the aneurism being a mere depression like a watch-glass or half-an-egg; or there may exist a constricted or defined neck, leading to a tumour bulging from the walls. The size of the opening may vary from a couple of inches across, to one capable of admitting only a probe. The neck is, in a few cases, described as hard and cartilaginous; in others, as being smooth and regular, or jagged and irregular. The walls of the tumour may be formed by the dilated and thin walls of the heart; or by the walls considerably thicker than natural, and altered in texture. A very usual condition to find is that the walls of the sac consist, proceeding from within outwards, of endocardium; fibroid tissue, with or without portions of muscular tissue; and pericardium. This condition was described as occurring in eleven cases. In eight cases the walls were said to consist only of the endocardium and pericardium, with fibroid tissue between; but it was found that at the base of the tumour, in all these cases, all the layers of the heart-tissue were present, and that it was only towards the apex of the swelling that the muscular layers disappeared. In three cases the walls of the aneurism were said to be composed of a thin membrane, which appeared to consist of endocardium and pericardium only. In three cases the walls were of cartilaginous consistence, with bony plates interspersed in the tissue. The thickness of the walls of the sac varied from that of paper to three lines or more. In fourteen cases the wall of the tumour was strengthened by the adherent pericardium. The aneurismal cavity in the majority of cases was lined by smooth membrane; but in a few instances, apparently of acute formation, the walls consisted

of muscular fibres, torn and separated by the blood which had been extravasated amongst them. The contents of the sac are generally in the form of blood-clots or layers of fibrin, the outermost layers of which may be more or less organised and adherent to the wall.

Seat.—Of the 56 cases already alluded to, 53 were in the left ventricle, 3 in the right ventricle, and 1 in the right auricle. Of the 53 cases in which the aneurism was situated in the left ventricle, 23 occupied the apex, 11 the base, and 17 were in intermediate situations. Several cases have been recorded, in which the aneurism was situated in the muscular septum between the ventricles; in the 'undefended space;' or at the base immediately below the aortic valves. A case of the last-named form was recorded by the writer in the third volume of the *Transactions of the Pathological Society*. These two last forms are generally associated with endocardial inflammation and ulceration.

SYMPTOMS.—In 13 of the 56 cases referred to, the aneurism was not discovered until after death; no mention being made of signs or symptoms of its previous existence. In the remaining cases, symptoms, more or less marked, indicative of heart-disease were present. These symptoms were chiefly—pain, dyspnoea, lividity of the surface, palpitation, and irregularity of the pulse. In 10 cases murmurs were heard, accompanying or replacing the sounds of the heart. We thus see that the symptoms of aneurism are such as may exist in common with other lesions of the heart; and it is extremely doubtful, except in presence of some special circumstances indicative of this condition, whether we have at our command the means of diagnosing the existence of cardiac aneurism. The writer not long since saw, with Dr. Holman, of Reigate, a case of grave heart-disease, in which extended dulness to the left and below the usual situation of the apex-beat, with a feeble impulse in the same situation, led to a suspicion of the probable existence of cardiac aneurism.

PROGRESS, DURATION, AND TERMINATIONS.—Pathological testimony fully justifies the inference that certain cardiac aneurisms—such as those which originate in inflammatory softening, ulceration, or the opening of cysts into the cavities of the heart—are acute in their formation. But the like evidence further testifies that the formation of most other aneurisms, and the progress of all, are of a slow or chronic character. Still, it would seem to be difficult if not impossible to determine the duration of the disease in any given instance, inasmuch as many cases, for example, have been found in the *post-mortem* room, which had not given rise to any special symptoms; whilst in other cases the pre-existence of heart-disease before the formation of aneurism rendered it equally impossible to fix a date for the development of the latter special disease.

Death may result from the disturbance of the heart's action, induced by the presence and extent of the disease; from the aneurism opening into the pericardium; or from its burrowing in the wall of the heart, and opening into another cavity of the organ different from that in which it originated. Lastly, one or two cases are recorded in

which a cure of the disease had apparently been effected by the walls of the sac becoming indurated or calcified.

DIAGNOSIS AND PROGNOSIS.—Seeing how extremely obscure the clinical history of these cases is, it would be impossible to speak more definitely either as to the diagnosis or the prognosis of the disease than has been done under the preceding head.

TREATMENT.—The treatment of cardiac aneurism must be such as would be adopted in any other form of grave heart-disease, and according to the circumstances of each case. We can only seek to mitigate the more urgent symptoms, whether local in the heart itself, or more generally affecting the distant organs.

R. QUAIN, M.D.

HEART, Apoplexy of. See **HEART, Hemorrhage into Walls of.**

HEART, Atrophy of.—**DEFINITION.**—A diminution in the size and weight of the heart as a whole; or a diminution in size of one part of the heart in relation to the whole organ.

ÆTIOLOGY.—The causes of atrophy of the heart are either *general* or *local*. With respect to the *general* causes of atrophy, the heart is found reduced in volume together with the other organs of the body, in cases of marasmus, of phthisis, of syphilis, cancer, &c. Probably one of the smallest hearts on record—one which weighed but $3\frac{1}{2}$ ounces—was found by Dr. Church in the body of a woman aged forty-seven, who died of cancer of the pylorus, after an illness characterised by 'gradual starvation' of more than seventeen months' duration. With reference more especially to phthisis, as affecting the size of the heart, an analysis of 171 cases made by the writer at the Brompton Hospital, showed that this organ was below the average weight in 54.4 per cent. Diseases of a sub-acute character, such as typhoid fever when protracted in its course, may lead likewise to wasting of the heart. The heart is also occasionally congenitally small.

The *local* causes of atrophy of the heart are chiefly two, namely (1), pressure by pericardial adhesions upon the heart in certain cases of generally impaired health, by mediastinal tumours, by fatty growth beneath the pericardium, and other conditions; and (2) interference with the circulation in the coronary arteries, as in the conditions just enumerated, or as a result of malformation or of disease of the vessels themselves.

Partial atrophy of the heart, when it occurs, is generally referable to insufficient blood-supply from vascular disease or local pressure; or to fatty infiltration.

ANATOMICAL CHARACTERS.—The heart in simple atrophy presents a general uniform diminution in size, as regards both its walls and its cavities; and in its weight. In local atrophy, a portion of the cardiac wall, more or less extensive, or of one of the divisions or cavities of the heart, may be found to be below the ordinary dimensions. The colour of the atrophied heart may be normal; it is frequently pale; and it is occasionally of a deep reddish-brown. The pericardium, not shrinking proportionately with the muscular

substance, may present a puckered, opaque, and oedematous aspect, 'like a withered apple' (Laennec); and for the same reason the coronary vessels may be tortuous and prominent. The consistence of the walls is generally firmer than natural; and the muscle may be even tougher, except where the atrophy is due to the presence of fat, in which case the fibres are friable, and on microscopical examination present the appearances of fatty degeneration. If simple atrophy of the heart, the muscular fibres undergo diminution in volume; and they may also be actually reduced in number. Atrophy of individual muscular fibres is also found as the result of interstitial fatty or fibroid growth; and this when extensive has been somewhat erroneously named '*yellow atrophy*'. Another variety, which is most frequently found in the marasmus of old age, is known as *brown atrophy* of the heart. In such cases the muscular tissue is of a dark or dirty reddish-brown colour, which proves on microscopical examination to be due to the presence of numerous shining yellow or brown pigment-particles within the muscular fibres, and especially abundant either around the nuclei or between the ultimate fibrille.

SYMPTOMS. The symptoms and signs of atrophy of the heart are those which might be expected to result from diminished size and power of that organ. The characteristic phenomena are those of feeble circulation. The physical signs are chiefly diminished precordial dulness; a feeble impulse, the apex-beat being within and above the usual situation, diminished area of audible sounds, and a small, weak pulse.

DIAGNOSIS.—The above signs and symptoms, in association with general wasting, afford sufficient grounds for the diagnosis of atrophied and feeble heart. Emphysema, pericardial effusion, and other causes of diminished cardiac dulness and weakness of impulse, must be excluded by the ordinary modes of investigation. There are no special means by which *partial* atrophy of the heart can be diagnosed, except, possibly, that the presence of this condition may be assumed where the functions of the organ are disturbed in the absence of valvular or other of the more common forms of cardiac disease, sufficient to explain the symptoms.

TREATMENT.—The treatment of atrophy of the heart is the treatment of the primary disease upon which it depends, so far as is possible.

HEART, Congenital Misplacement of.—**SYNON.**: *Ectopia Cordis* (Breschet), *Ectocardia* (Alvarenga).

The heart is occasionally found to occupy a wrong position, and such misplacement may either be within the cavity of the thorax, or external to it.

1. Of the *internal* malpositions—*ectopia cordis*

Intrathoracic or ectocardia intrathoracica—the most common is that to which the term *dislocatio cordis* has been applied, in which the heart is in a very similar position on the right side of the chest to that which it should occupy on the left. This condition may coexist with transposition of the other viscera of the body, or it may occur alone. Instances of the former kind have long been placed on record, cases having been met with in Rome in 1643, in Paris in 1650, and in London in 1694. When the heart is misplaced, the aorta generally follows an irregular course, crossing the right bronchus and passing down to the right side of the bodies of the vertebrae; and the right carotid and subclavian arteries are given off as separate vessels, while the brachiocephalic trunk is situated on the left side. In some instances, however, the vessels at the arch are not transposed; whilst in others the aorta, after passing over the right bronchus, crosses the spine and follows its usual course to the left of the bodies of the vertebrae. In cases of transposition the heart itself may be well-formed, or it may be very imperfectly developed.

In another kind of misplacement, *mesocardia*, the heart is situated more in the median line than natural—a position which it occupies in the fetus at the earlier periods. Cases have also been recorded in which the organ occupied a transverse, and an antero-posterior direction.

2. Of the *external* misplacements, those in which the heart is situated external to the thoracic cavity—*ectopia* or *ectocardia extrathoracica*—the most common is that in which, from deficiency of some part of the sternum, the organ lies in front of the chest—*ectopia cordis* or *ectocardia pectoralis*. In other cases, from deficiency in some portion of the diaphragm, the heart is placed in the abdomen, either lying in the cavity, or, if the integuments are partially defective, in a sac in the pre-cordia—*ectopia cordis* or *ectocardia abdominalis*. In a third form the heart lies at the root of the neck—*ectopia cordis* or *ectocardia cephalica*. Of these forms, examples are related or referred to in the memoirs of Brochet and Alvaranga, and various others have been published since the appearance of the memoir of Brochet.

SYMPTOMS, DURATION, AND TERMINATIONS.—When the heart is well-formed, its misposition within the thorax does not necessarily cause such interference with its functions as to be productive of symptoms, or materially to curtail the duration of life. Indeed, cases are on record in which the heart and other viscera have been transposed in persons who had never presented any signs of disorder of the circulation, and who lived to very advanced ages. When, however, the organ is also defective, and especially when the displacement is external to the thoracic cavity, life is usually only of short duration—though some remarkable cases of external displacements are on record, in which the patients survived to advanced ages.

Malformation of the Pericardium.—Closely allied to the cases of misplacement of the heart are those in which the organ, though occupying its natural position, is not covered by the pericardium, but lies in contact with the lung in the left pleural cavity. Of this form of ano-

mally various instances are recorded—the first undoubted case of the kind being probably that represented by Dr. Baillie, in 1775. The defect seems to consist in the pericardium, which is apparently reflected from the external coat of the aorta, not being prolonged so as to cover the front of the heart and become attached to the diaphragm. The imperfectly developed membrane is represented by a kind of loose fold, or pocket, which is found on the right side or upper part of the heart.

EFFRENA.—This condition does not seem materially to interfere with the functions of the organ. Cases are recorded in which the subjects lived to middle age; and the writer has himself seen it in a man who died of heart-disease at seventy-five. T. B. FRACOCK.

HEART, Congestion of.—Attention was first directed to this morbid condition of the heart by Sir William Jenner (*Medico-Chirurgical Transactions*, vol. xliii. p. 199). The coronary veins, like the veins of other parts, are subject to engorgement, when the flow of the blood from them into the right auricle is interrupted. The most common cause of this is dilatation and distension of the cavities of the right side of the heart, which conditions are themselves usually due either to emphysema or to valvular disease of the heart. Disease of, or pressure on, the trunks of the coronary veins may be regarded as less frequent causes of the same result.

ANATOMICAL CHARACTERS.—Congestion of the heart is recognised, when recent, by the fulness of the veins on the surface of the organ, oedema of the loose connective tissue at the base; and ecchymosis of the pericardium and endocardium. The pericardial sac contains some serous or sero-sanguinolent effusion, and the mouth of the coronary sinus may be found to be dilated. When the congestion is slight, gradually developed, and of long standing, the venous fulness gives rise to an increased formation of connective tissue in the walls of the heart, which become, in consequence, tough and indurated, whilst the dilatation of the cavities, with which the congestion is associated, is rendered permanent by the same cause. When divided with the knife, the cardiac walls do not fall inwards, their substance feels like a piece of leather, and the section has a smooth homogeneous appearance. Microscopically, the connective tissue seems to be increased in quantity; and the muscular fibres are in a condition of granular, fatty, and pigmentary degeneration.

Congestion of the heart possesses no direct clinical relations. J. MITCHELL BRUCE.

HEART, Connective-Tissue Hypertrophy of.—**DEFINITION.**—An excessive development of the connective tissue which exists between the muscular fibres of the heart, causing an increase of the volume of the organ.

ANATOMICAL CHARACTERS.—In connective-tissue hypertrophy the heart is enlarged more or less uniformly as regards the walls of its several cavities, and usually greatly, weighing in some instances as much as forty ounces. The thickness of the walls is increased, as in simple hypertrophy; and their density and

THE HEART, CONNECTIVE-TISSUE HYPERTROPHY OF; AND DEGENERATIONS OF.

existence are such that they present a firm, tough, leathery character. When cut the edges do not collapse, but continue stiff and prominent. The colour of a heart in this condition may vary from pale buff to deep purple, according to the amount of connective tissue and of blood present in the vessels. Microscopically there is seen—not the usual limited amount of intermuscular fibrillar tissue and connective-tissue cells, but a decided hyperplasia of these elements, in the form of connective tissue, of which all stages of development may sometimes be observed, from the round and spindle-shaped cell to the perfect bundles of fibrillæ. Between the individual bundles of connective tissue lie the muscular fibres, which are also hypertrophied, but which are more or less compressed, and are occasionally in a condition of granular or fatty degeneration.

There is a certain amount of anatomical resemblance, but a very clear pathological distinction between this form of heart-disease and the change described by Sir William Jenner as fibroid disease of the heart resulting from congestion (*see* HEART, Congestion of). Connective-tissue hypertrophy may also to some extent be compared with the fibrosis described by Sir William Gull and Dr. Sutton as existing in the walls of arteries and other tissues.

ÆTIOLOGY.—Cases of hypertrophy of the heart have been described by several writers in which there was disease neither of the valves, vessels, nor kidneys to account for it, and which the writer believes to be due to the pathological changes here described. A remarkable specimen is preserved in the museum of St. George's Hospital, consisting of a heart weighing forty and a half ounces, which was removed from the body of an under-butler, in the post-mortem examination of whom nothing was found which could satisfactorily explain the occurrence of the enlargement. The writer is indebted to Dr. Whipple for an opportunity of examining this specimen, which was found by his friend, Dr. Mitchell Bruce, to possess the microscopical characters above referred to. This and similar cases exhibit no appearance of chronic inflammatory action, and thus differ altogether from examples of that form of fibroid degeneration which is described under a separate heading (*see* HEART, Fibroid Disease of). In the cases now described there is a simple hyperplasia of connective tissue, the origin of which cannot be fully explained. In Germany similar enlargement of the heart is said to have been more especially found in gnomons, and hence it derived a characteristic appellation. The existence of connective-tissue growth being thus determined the effect of its presence on the muscular tissue is obvious. The connective tissue, surrounding, as it must do, the muscular fibres, interferes with their free action, to overcome which there will be a natural tendency to increased action, and consequent hypertrophy of the muscular fibres themselves. It is very probable that it is to these two processes going on simultaneously that the great increase in the size of the heart is due.

SYMPTOMS AND DIAGNOSIS.—In a remarkable case recorded by the late Dr. Hyde Salter, which

the writer believes to have been of the nature here described, acute or severe cardiac dyspnoea and hæmoptysis, from which the patient had suffered for several weeks, were the most prominent symptoms. The heart-sounds were natural, except that the first was dull and defective. The pulse was 84. The symptoms increased in severity, and were aggravated by excessive epistaxis. The patient died after being in hospital for fourteen days. At the *post-mortem* examination the heart was found to be of great size, and there was no disease either of the valves or of the vessels or of the kidneys to account for it. In the case of the butler in St. George's Hospital, it is recorded that he continued going about until within a few days of his death. These and some like cases indicate that we can do little in the way of diagnosis beyond recognising the presence of cardiac hypertrophy by the usual signs; and if the hypertrophy be considerable, and if there be no valvular disease and no kidney-disease, we might not be far wrong in considering that the hypertrophy was caused by increase of some other element than that of the muscular fibres.

TREATMENT.—If the opinion be correct that this form of disease finds its origin in excessive alimentation, it would be well to place the patient in such circumstances as would prevent this, giving attention at the same time to other hygienic conditions. The more aggravated symptoms of cardiac disease must be treated on general principles. R. QUAIN, M.D.

HEART, Coverings of, Diseases of. See PERICARDIUM, Diseases of.

HEART, Degenerations of.—The degenerations that affect the heart may be enumerated as follows—1. Fatty; 2. Parenchymatous; 3. Albuminoid; 4. Pigmentary; 5. Cartilaginous; 6. Calcareous; and 7. Vitreous. The condition which has been called 'fibroid degeneration' of the heart is described under the heads of HEART, Fibroid Disease of; and HEART, Syphilitic Disease of.

1 **Fatty**—This form of degeneration of the heart being of special importance is discussed in a separate article. *See* HEART, Fatty Degeneration of.

2 **Parenchymatous.**—**SYNON.**: Granular degeneration, Cloudy Swelling; ? Parenchymatous inflammation.

ÆTIOLOGY.—This form of degeneration of the heart is generally met with in the acute specific fevers, especially typhus, typhoid fever, diphtheria, and septicæmia; and is probably referable to the action either of the poison or of the high temperature attending the disease-process upon the muscular substance.

ANATOMICAL CHARACTERS.—The disease generally attacks the heart as a whole. The organ appears somewhat enlarged, extremely soft—friable as well as friable, and of a dirty grayish-red colour. The pericardium is ecchymosed, dull, and swollen, and the epicardial fat has more or less completely disappeared. Microscopically, the muscular fibres are found to be dull and granular swollen, and variously ruptured; their

striations are indistinct; and the addition of acetic acid removes many of the granules from the fibres, whilst it brings more distinctly into view a few fatty globules, and frequently an increased number of pigment-particles.

SYMPTOMS.—Inasmuch as parenchymatous degeneration of the heart is usually but a complication of some acute specific disease, the condition of the patient is one of great febrile prostration with cardiac asthenia. The physical signs, which are regarded as more distinct evidence than the symptoms of the condition of the heart, are—feebleness, advancing to complete absence, of the apex-impulse, or more rarely palpitation; and progressive weakening, and finally loss of the first sound. The pulse has been described as corresponding with the condition of the heart, except in some cases where it is imperceptible, although associated with cardiac palpitation.

COURSE AND TERMINATIONS.—The course and terminations of granular degeneration of the heart are inseparable from those of the primary disease. In typhus the average date of the appearance of the symptoms and signs just described is the sixth day of the fever, and they usually cease on the fourteenth day. A large proportion of cases prove fatal at or before that time.

PROGNOSIS.—The existence of this kind of degeneration of the heart adds seriously to the gravity of a case of fever, and the danger increases with the rate and weakness of the pulse, and the feebleness of the cardiac impulse and first sound. The return of the latter under treatment justifies a favourable prognosis.

TREATMENT.—The treatment of parenchymatous degeneration of the heart is in no respect different from that of the fever in which this condition originates. The appearance of the characteristic symptoms and signs of the cardiac affection is, however, to be regarded as an important indication for the use of alcoholic stimulants, which are, as a rule, well borne in such cases, and act very beneficially.

3. **Albuminoid.**—This kind of degeneration has been said, with a certain amount of possibility, to have been found in the heart. It is certainly excessively rare.

4. **Pigmentary.**—Pigment-granules, in the form of shining yellow particles, are almost invariably found in the muscular fibres of the heart in chronic cardiac disease. In certain cases of atrophy known as 'brown atrophy,' as well as in the granular degeneration just described, these pigment-particles are decidedly increased in number, and collected towards the axis of the fibres. A somewhat similar appearance is seen in the heart in jaundice.

The condition is of purely pathological interest.

5. **Cartilaginous.**—Portions of the myocardium have frequently been described as 'cartilaginous' or 'fibro-cartilaginous,' but it would appear that in these instances the muscular tissue was replaced by dense firm fibroid tissue only. See HEART, Fibroid Disease of.

6. **Calcareous.**—Calcification of pericardial adhesions is not very rare; and in some of the recorded instances of this condition, plates of the same material have been found projecting

into the substance of the heart, appearing as if formed within the myocardium. Besides this class of cases, instances of true deposit of calcareous particles within the individual muscular fibres have been described. This appears in the form of small, pale, gritty deposits, taking the place of the normal muscular tissue on the surface, in which, on microscopic examination, the muscular fibres were found to have become solid and opaque, whilst hydrochloric acid or sulphuric acid removed the opacity with the evolution of gas, the addition of the latter acid also producing gypsum crystals. It is probable that in other recorded instances, the calcareous particles were situated outside the muscular fibres, and may have been the products of a caseous nodule, whether syphilitic or 'tubercular' in origin.

This form of disease appears to possess no special clinical relations.

7. **Vitreous.**—Vitreous, waxy, or colloid degeneration, as described by Zenker, occurs in the myocardium, as it does in the voluntary muscles. J. MITCHELL BRUCE.

HEART, Dilatation of.—DEFINITION.

Dilatation of the heart may occur in two forms, in the one it involves only a limited portion of the cardiac walls and constitutes an aneurism; in the other there is uniform enlargement of one or more of the heart's cavities, and dilatation in the usual acceptation of the word is present. To this latter condition, however, the names 'aneurism' and 'passive aneurism' of the heart were formerly applied. Dilatation is probably always associated with hypertrophy.

ÆTIOLOGY.—The occurrence of dilatation implies that the walls of the heart which yield, are too weak to resist successfully the internal pressure to which they are exposed. This defective relation may be due either to actual enfeeblement of the heart's walls, which renders them unequal to the task normally devolving on them; or to excessive blood-pressure, which even the healthily-constituted walls are unable to withstand. The enfeeblement of the heart may be a consequence of fatty or other degeneration; or, as is probably more frequently the case, may be inherent but unconnected with visible textural disease. The excessive blood-pressure may be dependent on actual obstruction to the circulation which the heart is called upon to surmount; or on undue rapidity of action which (other things being equal) implies an unwonted expenditure of force. As a matter of fact, however, dilatation and hypertrophy are generally if not always associated; and the processes by which these combined conditions are attained are more complicated than the foregoing statement might lead one to suppose. It will be convenient, therefore, to consider certain cases *separatim*.

1. In obstructive diseases at the aortic orifice; in general stricture of the minute systemic arteries, such as occurs in connection with contracted granular kidneys; and indeed in all cases in which resistance is offered to the free discharge of blood from the left ventricle, progressive hypertrophy of the walls of that ventricle takes place. But the hypertrophy is complicated even from the beginning with dilata-

tion. The hypertrophy, at any rate at first, is simply compensatory, and may be taken as a measure of the excess of resistance which the heart is called upon to overcome. The dilatation, however, is in no sense compensatory, and is probably to be regarded as a measure of the inability of the walls to cope successfully with the extra work required of them. It is, moreover, obvious that the occurrence of dilatation, by increasing the area of resistance to the endo-ventricular blood-pressure, increases *pro tanto* the muscular effort requisite for the propulsion of the blood into the aorta; and by enlarging the capacity of the ventricular cavity and consequently the amount of blood to be discharged from it, on that account also throws additional labour on the muscular walls of the ventricle. Thus the hypertrophy and dilatation react on one another, and the hypertrophy, which was probably at first simply compensatory of the mechanical obstacle to the discharge of the normal contents of the ventricle, ends by becoming—or rather striving to become—compensatory not only of this but of the virtual weakness of the heart which dilatation entails.

2. In regurgitant disease at the aortic orifice, hypertrophy and dilatation of the left ventricle also take place. But in this case, while the hypertrophy probably reaches a higher degree of development than in simple obstruction, dilatation preponderates from first to last, and the ventricle attains larger dimensions than in perhaps any other form of disease. But to what are the hypertrophy and dilatation due in this case? There is no impediment to the escape of blood through the aortic orifice, and therefore *primâ facie* no need for compensative hypertrophy. There is no doubt that here hypertrophy waits on dilatation. The first effect of regurgitation is, that during diastole the ventricle becomes more rapidly and completely filled with blood than it does under other circumstances, and that the subsequent contraction of the auricle tends to distend it unnaturally with blood. The result is that, on the principles above enunciated, the walls of the ventricle have to encounter a larger area of pressure, and to expel a larger amount of blood than natural, and hence are called upon to make excessive effort, and hypertrophy ensues. Thus the tendency to dilatation causes the tendency to hypertrophy, and both acting continuously promote the progressive increase in the capacity of the ventricular cavity, and in the thickness of the ventricular walls.

It is probable in both cases, but more especially in the latter of them, that ere long the ventricle fails to expel the whole of its contents into the aorta at each contraction, and that the retention of this residual blood becomes an important factor in promoting dilatation.

3. The effects of continued violent action of the heart, whether caused by nervous influence or by muscular effort are much the same as those of obstructive disease. For both increased rapidity of contraction, and increased amount of blood to be expelled at each beat, other things being equal, imply increased expenditure of force; and the persistence of either or both of these conditions, therefore, the superoxygenation of hypertrophy and dilatation.

4. The above discussion relates especially to dilatation and hypertrophy of the left ventricle. But, *mutatis mutandis*, it applies with equal force to dilatation and hypertrophy of the other sections of the heart. Thus, in mitral valve disease, the left auricle undergoes hypertrophy and dilatation—the dilatation preponderating in regurgitant disease of the valve, the hypertrophy preponderating in obstructive disease.

5. In pulmonic valve disease the right ventricle becomes hypertrophied and dilated—the dilatation being greatest where there is pulmonic regurgitation, the hypertrophy being greatest where the disease is obstructive.

6. In tricuspid valve disease the right auricle suffers, becoming chiefly dilated in the presence of tricuspid regurgitation, chiefly hypertrophied when there is obstruction. And thus, also, just as when the systemic circulation is impeded the left side of the heart suffers, so when the pulmonic circulation is obstructed, the right side of the heart undergoes enlargement.

In all cases, therefore, hypertrophy and dilatation seem to result concurrently; but whether the one or the other condition preponderates, depends partly on the particular nature of the cause to which the hypertrophy and dilatation are due, partly on the inherent strength or weakness of the cardiac walls. In all cases, too, the other cavities of the heart, besides that primarily and directly implicated, suffer according to their position from the effects of the greater or less work which sooner or later is cast upon them.

The temporary dilatation which is described as occurring in acute febrile disorders, such as typhus, is due mainly to enfeeblement of the cardiac walls.

ANATOMICAL CHARACTERS.—In dilatation of the heart, the cardiac walls may be either thinner or thicker than natural, or may retain their normal thickness. It is a question, however, whether, excepting in the case of partial dilatation or aneurism, dilatation ever takes place independently of hypertrophy, for even as regards the auricles, where dilatation with attenuation is chiefly observed, there is reason to believe that the attenuation is not commensurate with the extension which accompanies it, and consequently that the total bulk of muscular tissue is increased. When dilatation is associated with no apparent change in the thickness of the walls, hypertrophy is of course present.

It must be mentioned, however, that it is often very difficult to determine on *post-mortem* examination the true relation between the thickness of the cardiac walls and the capacity of the cardiac cavities. For their apparent relation is largely dependent on the condition of the cavities at the moment of death, as to systole or diastole; and on the state of the heart as to cadaveric changes at the time of *post-mortem* examination.

The form which the heart assumes in dilatation is the same as that which it assumes in hypertrophy, and indeed as the two conditions are probably always associated, it is needless to endeavour to establish any distinction between them in this respect. If the dilatation be general, the form of the heart remains unchanged, but its size is uniformly augmented,

If the left ventricle be mainly affected, the heart appears not only enlarged but elongated, the left ventricle taking more than its due share in the formation of the cardiac apex. If the right ventricle be specially implicated, the heart becomes enlarged in its transverse diameter; it is more rounded in its contour as seen from the front than it should be; and its apex is obtuse, and either bifid, from the fact that the apices of both ventricles take an equal share in the formation of the cardiac apex, or formed wholly by the right ventricle. If the auricles be dilated, they constitute large masses on both sides of the root of the aorta and pulmonary artery.

The walls of the dilated heart vary not only in thickness but also in quality. Thus they may be preternaturally firm or preternaturally soft, they may be healthy in structure, or may present more or less degenerative change.

CONSEQUENCES OF DILATATION.—Dilatation of the ventricles, especially if it be considerable, is apt to disarrange the mechanism of the auriculo-ventricular valves. It was shown many years ago by Mr. Wilkinson King that even in mere temporary distension of the right ventricle a kind of safety-valve action of the tricuspid valve took place, in consequence of which regurgitation of blood was permitted from the ventricle into the auricle. And since his time it has been clearly demonstrated, both by clinical and by *post-mortem* evidence, that established dilatation of the right or left ventricle is liable to be attended with persistent regurgitation of blood through the corresponding auriculo-ventricular orifice. The defaulting valve under these circumstances has a natural aspect, but careful examination shows either that the orifice has undergone dilatation in company with the ventricle—the valve itself presenting no corresponding increase, or that there is a want of relation between the size of the muscular papillares and chordæ tendineæ on the one hand, and the capacity of the ventricle on the other, which interferes with the due closure of the valve.

It is obvious that if regurgitation becomes established, the usual consequences of regurgitation will presently ensue; namely, in connection with affection of the left side of the heart, dilatation and hypertrophy of the left auricle, and subsequently congestion of the lungs and pulmonary apoplexy, and in connection with affection of the right side of the heart dilatation and hypertrophy of the right auricle, fulness of the systemic veins, œdema, nutmeg liver, and congested, indurated kidneys. It is also obvious that, even if no regurgitant condition be developed, dilatation of heart, which implies feebleness of heart and imperfect circulation, must ultimately induce the ordinary remote consequences of heart-disease. A further consequence of dilatation and other cardiac affections attended with feeble circulation is the formation of thrombi during life, both in the heart itself, and in other parts of the vascular system. Mr. Wilkinson King has demonstrated that dilatation of the left auricle may cause compression of the left bronchus.

SYMPTOMS.—Since dilatation of the heart rarely if ever exists alone, but is associated with hypertrophy, valve-disease, degenerations, and other conditions, it is almost impossible to make any

definite statement with regard to the signs and symptoms by which its presence may be recognised. Still there is no doubt that dilatation is one of the most important factors of heart-disease, clinically considered; and that its super-vention materially affects the patient's condition, and prospect of life. Dilatation implies weakness, and as a rule over-distension of the implicated cavities with blood, which probably never becomes wholly expelled.

The *physical signs* of dilatation are necessarily in many respects the same as those of hypertrophy. The precordial dulness is increased in area—the extent and form of this area, and the situation of the apex-beat, being determined by the general size of the heart, and the relative dimensions of its component parts. In proportion, however, as dilatation preponderates over hypertrophy, the impulse of the heart becomes weak, and possibly to some extent diffused. In extreme dilatation, as in extreme weakness from other causes, the sounds of the heart, and especially the first sound, are feeble. And it may be asserted that generally the tendency of dilatation is to shorten the first sound, and to give it the characters of the second sound. It has nevertheless been observed over and over again that it is in the concurrence of hypertrophy and dilatation that the cardiac sounds are apt to attain their greatest intensity. The feebleness of the heart's action is generally attended before long by more or less irregularity, and even in the absence of valve-disease, a mitral or tricuspid systolic murmur, implying regurgitation, is apt to be established.

The symptoms of dilatation are to a large extent those of cardiac obstruction, and more especially of mitral disease. The patient complains of weight, oppression or uneasiness in the cardiac region, with probably a sense of fluttering there, and of a tendency to sighing respiration. He becomes short-breathed, and may have extreme dyspnoea. His face is apt to become livid, his surface pale or ghastly; his extremities cold and blue; and his pulse weak and irregular. Dilatation of the systemic veins arises sooner or later; and subsequently general œdema, pulsation of the veins in the neck, epigastric pulsation, and pulsation of the liver, together with the other usual consequences of heart-disease. The chief of these are—congestion of the lungs, with pulmonary apoplexy, cough, and expectoration of blood; congestion, enlargement, and tenderness of the liver, with jaundice; and congestion of the kidneys, attended with the discharge of scanty, high-coloured, heavy urine, containing albumen and possibly blood. Other symptoms referable to the nervous and digestive organs, which need not be enumerated, are also liable to supervene.

The symptoms will vary, of course, according as the left or the right ventricle is mainly affected. In the former case we are liable to have at first irregularity and feebleness of pulse with tendency to faint; then pulmonary complications; and at a later period, symptoms referable to the systemic venous circulation. The latter case is one of considerable interest; because in a large number of instances it is, in its most marked form, a consequence of emphysema of the lungs, or of

other analogous conditions, and moreover is apt to come on very rapidly. Under these circumstances, there is necessarily much dyspnoea, but the systemic venous and capillary systems speedily become over-loaded; extreme cyanosis often develops rapidly; and, before long, all the other symptoms referable to disease of the right side of the heart become established; namely, pulsation of the veins in the neck, epigastric pulsation, pulsation of the liver, general anasarca, with perhaps petechial extravasations, jaundice from atonic liver, and albuminuria from congestion of the kidneys.

PNEUMONIA.—There is no doubt that some degree of dilatation of the heart, and more especially of the right ventricle, may arise, either from over-exertion, or from functional disturbances, and in connection with pulmonary disorders. But such dilatation is for the most part temporary or remediable; and only by continuance of its cause becomes established and a matter of serious importance. In the same way there is no doubt that the dilatation which comes on in the course of organic disease of the heart or lungs, or of other organic diseases which influence the action of the heart, is remediable within certain limits by due attention to the conditions under which it arises. Nevertheless it is certain that the presence of dilatation of the heart in connection with other diseases, more especially those of the heart, lungs, or kidneys, is a grave source of danger; and that in the great majority of cases it is of fatal omen, aggravating the patient's cardiac symptoms, and hastening his death.

TREATMENT.—The treatment of dilatation of the heart merges in that of the other cardiac conditions with which it is associated, and in that of other diseases in the course of which it may have supervened. It may be stated, generally, however, that the treatment is that of cardiac debility, and of distension of the heart with blood.

The chief indications, therefore, are rest of mind and body; avoidance of exposure to cold and wet; the exhibition of ample nutritious and readily digestible food; due attention to the action of the bowels, kidneys, and skin, and the employment of medicines likely to regulate and strengthen the action of the heart. For the last purpose digitalis in small doses is universally acknowledged to be of great value. And it is in most cases desirable to combine the digitalis with iron, or some vegetable tonic. Ammonia and other diffusible stimulants are often called for, and are of great service. In cases where there is much lividity, and evidence of stagnation of blood in the right side of the heart, removal of blood by venesection may be of use.

When the dilatation is due to pulmonary disease, this of course requires primary and especial treatment.
J. B. BAISTOW.

HEART, Displacements of.—Besides the displacements of the heart that occur as the result of disease, there are certain changes of position which this organ undergoes in health. The most important of these physiological displacements of the heart are—first, its vertical

movements in respiration; and, secondly, the alterations in its situation corresponding with changes in the bodily posture. The present article, however, will deal only with the former class, or abnormal displacements of the heart.

ÆTIOLOGY.—The heart may be congenitally displaced—a condition which is described under the head of **HEART, Congenital Misplacement of**. These cases being excepted, the causes of displacement of the heart may be arranged in two classes—namely, (1) conditions that exert *pressure*; and (2) conditions that exercise *traction* upon the heart.

(1) The heart is *pressed* or pushed out of position by effusions of fluid—inflammatory, serous, or bloody—into either pleural cavity; by pneumothorax of either side, by intrathoracic tumours—whether mediastinal (including aneurism and abscess), pulmonary or parietal; by hypertrophied emphysema, or other causes of enlargement of the lungs, by extensive pneumonic consolidation; or by abundant pericardial effusion of any kind. Certain conditions of the abdominal contents produce a similar effect, for example—gaseous distension of the stomach and intestines; enlargement of the liver and other solid organs; abdominal tumours of all kinds; the pregnant uterus; and ascites, when considerable. Hernia of the abdominal viscera through the diaphragm, and abscesses connected with the diaphragm, also cause displacement of the heart.

(2) The heart suffers *traction*, or is drawn out of position during absorption of pleuritic effusion with imperfect expansion of the lung, on either side; by the contraction of pleuro pericardial adhesions, of pulmonary cirrhosis, or of cavities in phthisis; in collapse of either lung from pressure on the main bronchus; and in some forms of deformity of the chest from curvature of the spine.

MECHANISM OF DISPLACEMENT.—The causes just enumerated constitute in each instance what may be called the *displacing force*. When this force belongs to the first or *pressure* class, it acts against the surface of the pericardium and heart that is opposed to it, and presses or pushes it, *a tergo*, away from its own seat, in the direction of least resistance. Thus the heart is, speaking broadly, pushed towards the left by effusion into the right pleural cavity; towards the right by similar disease on the left side; downwards by tumours in the region of the base; and upwards by gaseous distension of the stomach.

On the other hand, when the displacing force is of the nature of *traction*, the heart is drawn *a fronte*, that is, towards the seat of the force. Thus, when a cavity in a phthisical lung is contracting, the pericardium and heart, as well as the walls of the chest, are displaced towards the healing area. It must be observed, however, that in this class of cases, actual traction, in the strict sense, is rare, and that the displacing force is, in reality, the atmospheric pressure; the heart and the other organs being 'sucked' towards the potential vacuum, in the same way as water is 'drawn' into a syringe. Still, in a very small number of cases, the pericardium does actually become involved in a healing pro-

cess in the lungs; and it and the heart are dragged towards the cicatrix.

Besides the displacing force, there are at work in dislocation of the heart certain other agencies, which contribute to the result, whether their effect be to increase or to diminish that of the chief cause.

a. The weight of the heart manifestly favours displacement in different directions, according to the posture. * Thus, in the erect posture, it favours downward, and limits upward displacement. However, the weight of the heart is comparatively insignificant, and may be practically disregarded.

h. The resistance, positive or negative, of neighbouring parts must be taken into account. The heart when disturbed from its position will move in the direction of least resistance. Thus it cannot be displaced to any extent either forwards or backwards, but is moved with comparative ease towards either pleural cavity. The resistance inferiorly is greater under the right half of the diaphragm than under the left. On the other hand, the resistance around may become negative; for example, in left pleural effusion the corresponding half of the diaphragm is pushed downwards, and the accompanying downward displacement of the cardiac apex is thus increased.

c. The heart is attached at its root; and, speaking broadly, this is a fixed point, at the right and upper extremity of the long cardiac axis. This attachment will limit and otherwise modify displacements of the heart in all directions, especially downwards. Round this point as a centre, and with the long axis as the radius, the apex of the heart will describe an arc of a circle, cutting the surface of the chest in the left axilla, the left submammary region, the epigastrium, the right submammary region, and the right axilla.

d. The tendency that the heart has to rotate or roll on one or other of its axes is also affected by its attachment at the root. If the heart lay free in the pericardial cavity, there would be no limit to such rotation under the influence of pressure or of traction. The base being fixed, rotation is greatly limited, and does not occur to any extent except around the longitudinal axis; the left ventricle, for example, being rotated more forwards or more backwards, as the case may be. Rotation round the transversal-horizontal and the antero-posterior-horizontal axes is very limited.

ANATOMICAL CHARACTERS AND EFFECTS.—The only essential change that the heart is found to have undergone in displacement is an alteration of its relations to the surrounding parts. The softer parts of the cardiac wall, however, such as the auricles, are sometimes compressed to a moderate degree. The pericardium is partly dilated and partly stretched. The great vessels at the base of the heart and at the root of the neck may be elongated, shortened, twisted, or bent, according to the particular form of displacement; and the circulation within them impeded. The neighbouring organs are variously displaced and compressed. One of the effects often seen after displacement is permanent fixation of the pericardium and heart in various

new position, for example, in the pleural cavity, on the disappearance of the original cause.

The effects of displacement of the heart upon its functions differ greatly in the two classes of dislocation to which we have referred:—

In displacement due to pressure, the heart is compressed between the displacing force and the resistance in other directions, and the dislocation is generally rapid. Fortunately, in most cases of such displacement the resistance is slight; and the heart, if healthy, suffers little or no real compression of its substance or evictions between the two forces, the mobile and compressible lung especially yielding before it. But if the heart be diseased—and especially if its walls be weak, degenerated, or dilated—moderate compression may cause embarrassment of the cardiac action and even fatal paralysis; and the rapidity or even suddenness with which displacement generally occurs when due to pressure—for example, in pneumothorax, is another and perhaps the principal cause of this embarrassment.

On the other hand, when the heart is drawn out of its normal situation towards a phthisical cavity, or towards either pleural cavity from which an inflammatory effusion is being absorbed, the displacement occurs, not because there is want of space, but because there is excess of space within the thorax. The process is also very gradual. The effects, therefore, upon the functional activity of the heart may be said to be few, though the unusual pulsation may be a source of inconvenience, and even of anxiety to the patient. In very rare cases, the heart and pericardium when thus displaced, may be involved in the fibrotic process going on in the lung or pleura, and the adhesions thus established may ultimately interfere with the cardiac action.

SYMPTOMS.—In displacement of the heart, special symptoms are frequently slight or altogether wanting, or they are inseparable from the symptoms of the original cause. This may be said to be almost invariably the case when the displacement is due to gradual traction, as in phthisis. In the pressure class of cases, on the contrary, there are frequently developed, and that rapidly or suddenly, symptoms due to compression of the heart, such as a sense of distress, stifling, and pain over the precordium or at the epigastrium, or even true angina; dyspnoea, perhaps amounting to orthopnoea; palpitation; blueness of the surface; and irregularity and feebleness of the pulse. When the displacement is due to upward pressure from gaseous distension of the stomach and intestines, the above symptoms may be associated with flatulence or 'splanchnic,' and are relieved by the erect posture, eructation, vomiting, and the administration of carminative and absorbent remedies. If this condition be not removed within a short time, it may become aggravated, pass into a state of collapse, and end in death.

VARIETIES AND PHYSICAL SIGNS.—The varieties of cardiac displacement, according to the direction in which the dislocation occurs, may, for clinical purposes, be said to be as follows:—towards the *left*, towards the *right*, *downwards*, *upwards*, *backwards*, and *forwards*. It must be observed, however, that this is only a broad

general classification, and that the heart is very rarely displaced in an absolutely horizontal, or in an absolutely vertical plane. The exact direction taken in each variety will now be described, as well as its special causes, and the physical signs by which it may be recognised.

1. **Displacement towards the Left.**—This, the most common variety of marked cardiac dislocation, is most frequently caused by contraction of the left lung from any of the conditions already enumerated, and effusions into the right pleural cavity. Right pneumothorax, and tumours connected with the right side of the chest, with the mediastinum, or with the right lobe of the liver, are less common conditions that lead to the same result. The distance towards the left to which the heart is dislocated varies: the extreme limit being probably the vertical axillary line. During its progress towards the left, the heart is rotated around its longitudinal axis, so that the right ventricle is more exposed anteriorly, and the apex is moved, at first somewhat downwards, and afterwards upwards.

The visible and palpable impulse is found to the left of its normal situation, and either lower or higher than it, or on the same level with it, according to the degree of displacement. In some cases due to contraction of the left lung, the impulse may be found in any one or in all of the left intercostal spaces from the base to the apex of the heart, and of different rhythm in the different spaces. If the displaced heart be the seat of valvular disease, thrill may be felt in an unusual situation, for example, in the left axilla. The area of percussion-dullness is altered in outline, being invaded on the right side either by the dullness due to effusion there, or by resonance due to pneumothorax or to encroachment of the right lung-border; whilst it is either transposed towards the left axilla, or blended with unnatural dullness over the left lung. The cardiac sounds are reduced in loudness over the normal precordium, whilst they are unnaturally loud towards the left axilla and up the left front. Structural murmurs if present are similarly transposed, as regards the seat of their greatest intensity and the lines of their convexion. A systolic murmur may be developed at the base of the heart from distortion of the great vessels.

2. **Displacement towards the Right.**—This form of dislocation of the heart is the result of effusion into the left pleural cavity, of contracting processes connected with the right lung or pleura; of left pneumothorax; and of tumours of the left side of the chest or in the mediastinum. The heart may be displaced towards the right side until the impulse is found in the axillary region. During its lateral movement, the heart is rotated on its longitudinal axis in such a manner that the left ventricle is more exposed; and, at the same time, the apex is first depressed towards the epigastrium, and afterwards raised towards the right axilla, as the displacement increases.

The physical signs correspond closely with those enumerated under left displacement—the two sides being, of course, exactly reversed. The cardiac impulse is most frequently transferred to the epigastrium and the region between that

and the right nipple. A new area of pulsation is sometimes developed in the second and third right interspaces, close to the sternum, and indicates the displaced position of the right auricle, if praxystolic, or of the aorta, if systolic and followed by palpable shock in diastole. The description of the auscultatory phenomena, as regards both sounds and murmurs, does not require to be repeated.

3. **Displacement Downwards.**—This is an exceedingly common form of cardiac displacement, though seldom extreme in degree. It is the constant result of hypertrophied emphysema of the lungs, and may also be caused by the downward pressure of tumours at the base of the heart, such as aneurism, and by collapse of the stomach and intestines. Displacement of the heart downwards is limited by the diaphragm, and by the attachment of the pericardium and great vessels at the root of the heart. At the same time the apex may either move somewhat towards the left in its descent if the downward pressure be uniform, as in emphysema; or it may ascend somewhat towards the left if the pressure be exerted chiefly upon the base.

The ordinary cardiac impulse is generally quite imperceptible in this form of displacement, on account of enlargement of the lungs; or it is greatly weakened, and situated in the sixth left space, or lower, to the left of its normal position. A new area of systolic pulsation is perceptible in the epigastrium, generally well marked, and connected with the right ventricle. The precordial dullness is usually completely replaced by pulmonary resonance; or, more rarely, confused by the dullness of some form of mediastinal tumour. The cardiac sounds are feeble, or absent, over their usual seat; and are heard, instead, over the epigastric triangle and the lower left cartilages.

4. **Displacement Upwards.**—The many abdominal causes of this form have been already mentioned, as well as the symptoms due to compression of the heart which characterise it when so produced. The heart, as a whole, is moved upwards in the chest, and at the same time the apex passes more or less towards the left, and the right ventricle may become somewhat more exposed anteriorly.

The cardiac impulse is elevated until it is found on the nipple-level, or even higher; or it is lost, along with the area of percussion-dullness, behind the inferior border of the left lung. The sounds of the heart are transposed upwards and weakened. The displacement of the cardiac apex towards the left axilla in pericardial effusion is described elsewhere. See PERICARDIUM, Diseases of.

5. **Displacement Backwards.**—This variety of displacement of the heart is very uncommon; and when it does occur, is generally referable either to abundant pericardial effusion, or to backward curvature of the spine (kyphosis) in the dorsal region. A certain amount of backward displacement is, however, not so rare in extensive excavation of the left lung, in association with other forms of dislocation. The base of the heart is then the part most transposed into the left paraspinal groove, and the apex is tilted somewhat forwards as well as elevated.

The physical signs of backward displacement are those of the cause of the malposition rather than any that can be referred to the condition itself.

6. Displacement Forwards.—Displacement forwards is also very rare, although it is frequently simulated by bulging of the præcordium in enlargement of the heart. The chief cause of it is the presence of a tumour in the mediastinum—especially aneurism of the descending aorta, or enlargement of the bronchial glands. The amount of actual transposition is necessarily exceedingly small, the anterior border of the lungs being compressed or pushed aside, but the further progress of the heart forwards being arrested by the anterior wall of the chest.

The physical signs are, therefore, increase of the area and strength of pulsation and of percussion-dulness over the præcordium, bulging of the same in young subjects, and increased loudness of the cardiac sounds in that situation.

7. Complex Displacements.—It has already been indicated that displacements of the heart, strictly speaking, occur almost without exception in more than one of the directions described, and they may all, therefore, be said to be generally more or less complex. Dislocation at once upwards and towards either side is especially common, as the result of contracting processes in the apex of the lung.

DIAGNOSIS.—After the full account that has been given of the several forms of displacement of the heart, there ought to be no great difficulty in diagnosing them from each other, as well as from the conditions which simulate them. These must be carefully remembered. The chief of these are:—(1) physiological displacements, already referred to; (2) cardiac enlargement, especially when attended with bulging of the præcordium; (3) pulsating tumours of the chest and abdomen, particularly aneurism of the aorta; (4) adhesion of the pericardium, and (5) atrophy of the lungs from any cause.

TREATMENT.—The rational treatment of displacement of the heart would be to remove its cause; but when the cause is of the nature of friction, treatment is very rarely called for, even if it were possible. In displacement due to pressure, on the contrary, treatment is often urgently indicated, perfectly practicable, and highly successful. The unpleasant sensation of pulsation complained of in some instances of displacement—for example, in phthisis—is frequently relieved by an assurance on the part of the physician that the palpitation is of no import; and by the application of a simple plaster, containing iron, belladonna, or opium. HEART, Embolism of. See HEART, Thrombosis of.

HEART, Fatty Degeneration of.—SYNON.: *Dégénérescence graisseuse du Cœur*, Ger. *Fettige Metamorphose des Herzens*.

DEFINITION.—The process by which the muscular fibres of the heart are converted into a granular fatty matter. The term is also used to express the state of the heart in which this change has been accomplished.

ÆTIOLOGY AND PATHOLOGY.—The process by which the protein elements of animal bodies, in-

cluding muscular fibre, are converted into granular fatty matter, as well as the circumstances under which this change occurs, have been already so fully discussed under the head of **FATTY DEGENERATION**, that it is unnecessary to repeat what will be found there. It will suffice to say here, that when the process of nutrition is interfered with in the tissues of the heart, this change takes place, and is best illustrated in the *local or limited* form of disease, which occurs when the coronary circulation is obstructed. This is seen in cases of thickening or calcification of one of the trunks, or of the branches of these vessels, and is more marked by reason of the fact that the coronary arteries do not freely communicate with each other. The fatty change is found to occur in the more *diffused or general* form in those diseases in which the vital powers are lowered, as in certain forms of chronic cachectic disease, in poisoning by phosphorus, or after loss of blood. In certain other conditions, such as acute specific fevers, the tissue of the heart becomes softened, and under the microscope presents a granular appearance, which is believed by some pathologists to be an incipient stage of fatty degeneration. We might also refer to the more or less diffused form of fatty degeneration which takes place in cases of enlarged heart, the result, not, as Rokitsansky supposed, of a disturbance of the nervous functions, but of the fact that these enlarged hearts require a larger supply of the materials for nutrition than can be furnished to them by the coronary arteries, which in such cases are frequently themselves diseased, both at their origin and in their course. Lastly, fatty degeneration of the heart is found to occur after delivery in some instances, in which the organ had become enlarged during pregnancy.

Certain other circumstances connected with the origin of the disease require to be mentioned here. In reference to *sex*, the disease is more frequent in males, in the proportion of nearly two to one. With respect to *age*, in his original memoir on this subject, the writer found that nearly one half of all the cases observed were over sixty years of age. In the late Dr. Hayden's valuable work on *Diseases of the Heart*, the proportion stated of cases under sixty years of age shows a larger number of young persons whose hearts have undergone this change as a result of wasting disease—a result which is evidently due to the greater care with which microscopical examinations of the heart have been made in recent times. As regards social position, of thirty-three cases formerly noted by the writer, the subjects of the disease are stated to have belonged to the higher ranks in nine cases; to the middle class in eight cases; and to the lower class in sixteen cases. This enumeration contrasts with the proportion in which fatty growth appears on the heart; seven of fifteen cases belonging to the first class; six to the second; and only two to the third. Fatty degeneration and fatty growth on the heart are thus seen to occur under very different conditions. The latter is the result of the accumulation in the blood of the elements of fat; the former is the result of decay and disintegration.

ANATOMICAL CHARACTERS.—In fatty degenera-

tion the heart is found to be enlarged in about two-thirds of the cases recorded both by Dr. Hayden and the present writer. It is not unfrequently simply dilated. To find a fat heart of an average size, or even occasionally below it, is not a very exceptional occurrence. The colour of the heart's substance is pale, sometimes as pale as 'a dead leaf,' but more generally it is of a yellowish-brown or buff, or muddy pink colour. This discolouration is generally seen in spots or patches; and though the whole heart may be pale, the spots being still paler when seen beneath the endocardium, give the tissue a mottled look. The same appearance may be seen beneath the pericardium, and in the substance of the heart. With the progress of disease the spots run together, giving portions of the walls a uniform buff-coloured character, whilst the rest of the organ retains its ordinary aspect. The consistence also varies from that of mere flabbiness or softness, to such a condition as permits of the tissue being torn like wet brown paper. The organ then feels like a piece of wet chamois leather, or a wet glove. In other cases the heart retains in appearance much of its ordinary solidity, but the tissue breaks down on pressure, as does a lung consolidated by pneumonia. This is a state which more frequently occurs in hypertrophied hearts. In addition to these changes in size, colour, and consistence, others have to be noted. The fibrous character of the heart's structure, even to the naked eye, disappears, in some cases the tissue resembles that of a fatty or boiled liver. In other instances the cut or torn surface has a granular appearance, not unlike that of the lung in an early stage of grey hepatization. These different appearances may in a great measure be due to the greater or less fluidity of the oily matter present, as well as to the extent and degree to which the disease has advanced. Further varieties in appearance may be caused by the presence of a greater or less quantity of blood, or of its colouring matter, in the heart's texture or in its cavities, by which the lining membrane may in the latter case be dyed of a deep purple colour.

Microscopical characters.—The microscopical characters of this disease will be found so fully described under the head FATTY DEGENERATION, that it is needless here to do more than refer the reader to that article.

FIG. 22. Fatty Degeneration of the Heart. $\times 400$ diam.

All parts of the heart's fibres are subject to fatty degeneration, but not equally so. It is most frequently found in the left ventricle; next in the right ventricle; then in the right auricle; and least frequently in the left auricle. It is generally more evident in the columnar carinae, and in the inner layers of the muscular walls, than elsewhere.

Effects.—Of the structural lesions occurring in the heart when the seat of fatty change, one of the most important is *rupture*, which was found in twenty-five out of sixty-eight cases of fatty or softened heart, the histories of which were collected by the writer. Partial rupture leading to the formation of what has been called *cardiac apoplexy*, is another condition which has been described. The clot in such cases, if it lose its colour, may produce an appearance like an encysted abscess, and a consecutive false aneurism of the walls of the heart may be thus formed, as well as by simple yielding of a portion of the softened cardiac wall. The involvement of the columnar carinae may lead to imperfect action of the valves. Valvular disease itself is not often present in connection with fatty heart. Dr. Henry Kennedy, in a recent interesting work on this subject, points out that the valves are affected only about once in nine cases; and he further shows that, when the valves are affected, it is chiefly the aortic valves that are involved.

Of the effects of fatty degeneration upon the functions of the heart, the most prominent are those which exhibit the deficient powers of the organ. *Coma*, preceded or not by giddiness, has been described by several writers in connection with feeble powers of the circulation. Dr. Adams of Dublin has mentioned as many as twenty attacks in one of his cases of fat heart; and the writer has noticed the occurrence of even more frequent seizures. *Syncope*—'cardiac syncope' is a term very frequently used by the older writers; and it is a term which may be well applied to the condition of faintness which is frequently found in connection with fatty heart. In some cases the feeling of syncope amounts to nothing more than a simple sense of faintness—that the patient must fall if he do not lay hold of something. In other instances this symptom is accompanied by a feeling of impending death; and such patients do frequently die. In the cases collected by the writer, thirteen out of thirty-three died of what he proposed to call *syncope lethalis*, or 'fatal syncope;' and it would be possible, no doubt, now greatly to extend the number of cases that have proved fatal in this way. Death may result in such cases from cardiac failure, as indicated by a flabby heart containing blood in the left ventricle, or, where there is a less amount of degeneration, by irregular action or spasm, with emptiness of the ventricles.

Pain is another effect. It may occur independently of, or be associated with syncope—*syncope anginosa*. See ANGINA PECTORIS.

The *respiration* is considerably affected, in all cases of fatty degeneration, either as simple breathlessness, especially on exertion, or in that peculiar form which has been called *Cheyne-Stokes respiration*.

SYMPTOMS AND DIAGNOSIS.—There is no doubt

that many cases occur in which fatty degeneration is found in the heart after death, where its presence during life had not been suspected. This is more especially the case in those examples of exhausting disease in which the heart participates. In such cases the requirements of the system may not be out of proportion to the powers of the heart, and death may come on slowly and insidiously without our attention being attracted to the state of this organ. In a second class of cases, in which the heart suffers from some local cause, as, for example, from disease of the coronary arteries, whilst the system generally maintains its powers more or less fully, the balance between the system and the heart is lost, and diagnostic evidence of the change that has occurred in the central organ, sufficiently clear and pointed, may be traced without difficulty. Amongst the symptoms of the disease we then observe various modifications of the phenomena of drowsiness and coma; faintness and syncope; disordered respiration; pain in the region of the heart; and disturbed pulsation. For example, the patient complains in the earlier stages of being easily exhausted, particularly by mounting heights; he feels, he says, faint on reaching the top of the stairs; though not giddy, he feels he must fall, though not breathless or fainting, he sighs deeply and seeks the air. Any unusual excitement, a heated or a close atmosphere, produces the like effects. At the same time there is often experienced an uncomfortable feeling of choking or fullness in the chest. In the intervals the individual may be fairly well.

As the disease advances, the attacks become more frequent and severe, and often disturb and distress the patient at night. The temper is observed to become irritable. The expression of the features frequently appears anxious, and the countenance sallow. Copious perspiration from very slight causes, sometimes coldness of the extremities and swelling of the ankles, appear amongst the incidents of the disease. The pulse is generally affected; but how must no doubt depend in a great measure upon the part of the heart affected, and on the extent and degree of the disease. In the writer's opinion, intermittence and irregularity are the more frequent alterations, weakness is another; and slowness—often remarkable—is a third. Quickness of the pulse, more especially when it increases with age, has been dwelt upon by Dr. Kennedy as a symptom deserving of attention in the diagnosis of fatty degeneration. The irregularity may be constant. The writer has seen it present during the slight disturbances above described; and he has seen it disappear altogether when the patient was in tolerable health, to return as the effect of any depressing cause, the more marked because that cause may be far too inefficient to affect a sound heart.

The breathing is always more or less affected in cases of fatty degeneration of the heart. In some instances it is represented as a sense of choking or suffocation; the person feels as if he were breathing through a sponge. The difficulty in some instances is so slight as scarcely to be regarded; in others so severe that the smallest effort, particularly in mounting ascents, is most

painful. A peculiarity sometimes observed is that the ascent of a gentle height is distressing, while the person can read aloud without inconvenience. A character of the respiration first described by Dr. Cheyne of Dublin, and afterwards by Dr. Stokes, is by some regarded as diagnostic of fatty degeneration of the heart. It is thus described by Dr. Stokes: 'A form of respiratory distress peculiar to this affection (fatty degeneration of the heart), consisting of a period of apparently perfect apnoea, succeeded by feeble and short inspirations, which gradually increase in strength and depth until the respiratory act is carried to the highest pitch of which it seems capable, when the respirations, pursuing a descending scale, regularly diminish until the commencement of another apnoeal period. Dr. Hayden, in writing on this subject, mentions a case in which during the period of apnoea there was no change in the heart's action, a second case in which the action of the heart and the pulse underwent no change during the period of apnoea and dyspnoea; whilst in a third case, during the paroxysm of dyspnoea, the heart's action was remarkably irregular. It should be stated with regard to this symptom that, though frequently present, it is by no means characteristic of fatty degeneration only. It is by some said to be more frequently associated with disease of the aorta. Various explanations of this phenomenon have been given. Dr. Little (*Dublin Journal of Med. Sci.*, No. 91) believes that it is due to derangement of the dynamic adjustment between the right and left ventricles of the heart. Dr. Hayden (*op. cit.*) connects it with atheromatous or calcareous change with dilatation of the arch of the aorta, involving loss of elasticity in its walls. The late Professor Laycock thought (*Dublin Journal of Med. Sci.*, July 1873) that this phenomenon depended upon 'suspended palsy of the respiratory centre,' or 'a paresis of reflex sensibility of the mucous membrane of the lung.' See *Respiration*, Disorders of.

Another phenomenon, said to be diagnostic of fatty degeneration of the heart, is arcus senilis—a pearly crescentic opacity of the upper and lower portions of the circumference of the cornea, which must be distinguished from the opaque annulus which occasionally surrounds the entire cornea. Mr. Canton was the first to describe the nature of this change as fatty degeneration. It is quite true that when fatty degeneration is present in the cornea it may possibly be found in the muscular fibres of the heart and in the arteries. Still it by no means follows that the degeneration must exist in any particular part or organ, and therefore this appearance in the cornea cannot be regarded as at all pathognomonic of fatty degeneration of the heart.

As the disease progresses still farther, the symptoms become more marked; the various effects of feeble and languid circulation show themselves; angina may perhaps become fully developed; or the patient may be cut off suddenly by one or other of the effects connected either immediately or remotely with the lesion itself. Of eighty-three cases of 'fatty disease' of the heart collected by the writer, sixty-eight died suddenly.

PERCUSSORY SIGNS.—The physical signs that characterize fatty disease are not many. They are—a feeble impulse of the heart, proportionate to the extent and the degree of the disease; a feeble muffled first sound, under like conditions, sometimes scarcely audible. When the heart is enlarged, the impulse will be extended, and so likewise will be the dulness. A murmur may be present, as suggested by Rokitsansky, from degeneration of the aortic valve. The second sound is often distinct and clearly accentuated, as compared with the first.

DIAGNOSIS.—The diagnosis of the presence of this degenerative change in the absence of any alteration in the size of the heart must be founded upon a consideration of the symptoms and physical signs above described. When the heart is hypertrophied or dilated only, the presence of fatty degeneration is more difficult of diagnosis by its physical signs. We must then seek to trace how far the usually well-marked signs of hypertrophy of the organ are modified by those we have described as being present in, and characteristic of, fatty degeneration. The same observations will apply to dilatation or thinning of the walls. This special condition has its own well-marked phenomena, which will be found described elsewhere (see HEART, Dilatation of). These signs will be more or less modified in proportion to the degree and extent of any fatty change that may be present.

PROGNOSIS, DURATION, AND TERMINATIONS.—It is impossible to determine the duration of a disease the date of origin of which is in most cases very obscure. Still there are grounds for believing that persons with a certain amount of degenerated tissues in their hearts have gone on living during periods extending over thirty or forty years. On the other hand, death has occurred from fatty degeneration of the heart, determined *post mortem*, in which the entire absence of symptoms until a few months before the fatal event justified the opinion that the duration of the disease had not much exceeded the period just mentioned. When fatty degeneration occurs as the result of phosphorus-poisoning, or of certain exhausting diseases, the progress of the change, which can be determined, is rapid. In such cases, the morbid process is not confined to the heart alone, and therefore when death occurs, it cannot well be attributed solely to the condition of this organ.

Death from fatty disease of the heart is frequently sudden, the proportion being as five to one compared with other modes of death, this disease existing to a noticeable extent. The immediate causes of death are those which have been already alluded to when treating of the effects of the disease, namely, syncope, coma, and rupture of the heart; the first and last of these contributing nearly the whole number of those that die suddenly. Such facts indicate very strongly the necessity of avoiding any mental excitement or physical exertion which might lead to these results. Here it might also be well to remember, with reference to the administration of anesthetics, that chloroform has an especially depressing effect on the heart's action, and that when the heart's power is enfeebled by the disease which we are here describing, a very

small dose of this anesthetic, which would have little or no effect on a healthy heart, may prove fatal. This opinion was first expressed by the writer many years ago, and it has been fully confirmed by numerous cases of death which have occurred during the administration of chloroform.

PROGNOSIS AND TREATMENT.—The prognosis of fatty degeneration of the heart will depend in a great measure upon a knowledge of its cause and its extent. In cases where the disease originates in constitutional causes, such as in phosphorus-poisoning, and in cases where it is of the nature of involution—for example, after parturition—there is good ground for believing that, the cause being removed, the effect will cease, and a fairly healthy condition of the organ be restored. On the other hand when the coronary arteries are obstructed, and degeneration is thereby set up, or when nutrition generally is impaired, and all the tissues are more or less undergoing this change, the prognosis must be in the highest degree unfavourable, more especially so if in the latter case the patient cannot be placed in a condition by which this degenerative tendency may be counteracted. The treatment consists in the adoption of all the measures calculated to improve the general health—such as pure fresh air, wholesome food, and temperance, together with moderate exercise, either carriage, riding, or walking, if it can be accomplished without causing pain or breathlessness. Everything which may tend to lay stress on the heart's action, such as walking uphill or making efforts, or mental excitement, should be avoided. With reference to drugs, such tonics as can be best tolerated by the patient might be given. We may mention iron—especially dialysed iron—phosphorus in small doses, and strychnine. Special attention must be paid to the condition of the excretory organs, such as the kidneys and liver, which are liable to become congested when the cardiac action is feeble. Lastly, it may be said that in cases of syncope, in addition to the administration of the usual stimulants, galvanism applied from the back of the neck to the precordium by the interrupted current, has in a few instances been known by the writer to be useful. For further information on the subject of Fatty Degeneration of the Heart the reader may consult the complete and very valuable article by Dr. Hayden in his work on DISEASES OF THE HEART, and a memoir by the writer in the 33rd volume of the *Medico-Chirurgical Transactions* (1850). R. QUAIN, M.D.

HEART, Fatty Growth on.—S. NONN: Fr. *Hypertrophie graisseuse du Cœur*; Ger. *Fettige Infiltration des Herzens*.

DEFINITION.—The growth of fat on the surface and in the substance of the heart, in quantity sufficient to interfere with its functions, and thus to constitute a disease.

ÆTIOLOGY.—In our inquiries concerning the cause of this condition, we are met with the problem, still to be solved, Why are certain individuals, and certain parts of the body, more prone to the formation of fat than other persons and other parts? We can ascertain with some degree of certainty the circumstances which promote the formation of fat in general; and observe

variations collected by the writer and others show that when fat is thus formed throughout the system, the heart is likely to partake largely of the accumulation. We may accordingly refer to the article *ONMERT*, in which the causes of fatty growth in general will be found discussed.

Of fifteen cases of extreme fatty growth on the heart collected by the writer, eleven occurred in very fat individuals, and only one in a person who was described as being 'thin.' Age seems to exert a decided influence upon the formation of fat upon the heart. It is very scanty in infancy, and is rarely present in any quantity before the thirtieth year. *Corvisart*, however, quotes from Kerckring the case of a child whose heart seemed wanting, so great was the quantity of fat in which it was embedded. Of the fifteen cases just referred to, thirteen were above fifty years, and one only under that age. Males, according to the same data, are more liable to accumulation of fat on the heart than females, the respective numbers being as twelve to three.

ANATOMICAL AND PATHOLOGICAL CHARACTERS
A certain amount of fat-tissue, which is not inconsistent with health, occupies a definite position in the structure of the heart. It is seen most abundantly in the groove between the auricles and the ventricles, and as the distribution of this tissue bears a relation here, as in other parts, to that of the blood-vessels, it first appears in the course of the primary branches of the coronary arteries, then in the course of the secondary branches—that is, in the groove over the septum, which marks the boundary between the ventricles, and, lastly, it follows the distribution of the small lateral branches. These branches are more superficial over the right ventricle than over the left, hence the former is found always and more abundantly covered with fat. A fringe of fat is also found at the apex of the heart; and frequently around the margins of the auricles. A mass of superabundant fat will of itself be sufficient to press on and embarrass the action of the heart; but fat rarely exists in this abundance on the surface of the organ without insinuating itself between, and encroaching on, the muscular fibres. In this way the muscular portions of the walls of the organ become thinner and thinner, until the columns carnes may appear to arise from a mass of fat. This state constitutes what was once regarded as fatty degeneration of the heart, and which has also been called 'fatty metamorphosis'; but it is in many cases nothing more in reality than a simple hypertrophy of fat. In parts of hearts which are less affected, that is, where fat is not very abundant, simple striae of yellow tissue will be observed lying amongst the muscular fibres—an appearance often found in the auricles.

Microscopical appearances.—When a portion of heart suffering from fatty growth in a high degree is examined with the microscope, it will be found that where the growth is most advanced, that is, towards the external surface, very few muscular fibres can be seen, and that the very wide intervals between them are occupied by fat-cells. (See Fig. 23.) Proceeding inwards the muscular fibres become more evident; the fat-cells become fewer; and, finally, we reach

the muscular fibres beneath the endocardium, with a few fat-cells lying here and there amongst them. It is worthy of note that the fibres, though overwhelmed by fat, may still retain their organization. In all cases, however, the course and direction of the fibres are more or less modified and distorted. The fact that the fibres still exist, though concealed, affords an explanation of

FIG. 23. Fatty growth in the substance of the heart. $\times 400$ diam.

the persistence of the heart's action in those instances in which the muscular walls appear to a greater or less extent replaced by fat. It might also be mentioned that small masses of fatty tissue sometimes appear beneath the endocardium, varying in size from that of a pin's head to that of a pea. The writer has seen these little fatty tumours in cases where there was a considerable, but not an excessive, amount of fat upon the surface of the heart.

EFFECTS.—The fat accumulated on the heart and in its substance, may be supposed to act mechanically; and by its pressure upon the muscular fibres, on the nerves, and on the blood-vessels, to impede the function of the organ, embarrass its nutrition, and produce those effects, which may be briefly enumerated as—a languid and feeble condition of the circulation, with a sense of uneasiness and oppression in the chest; embarrassment and distress in breathing, drowsiness, even coma; syncope, perhaps angina pectoris, it may be death. Rupture of the heart sometimes results. Such an enumeration of evils, in which there is no evidence of any other lesion of the heart's texture, save an accumulation of fat, would suffice to render this condition a source of very grave import, but we cannot always be quite clear on the subject, because in the particular cases quoted we cannot be certain that some degeneration of the muscular fibres did not co-exist. It would be well, therefore, not to dwell too much on such effects as proceeding from and dependent on fatty growth alone.

DIAGNOSIS.—The presence of an excessive deposit of fat about the heart must, in a great measure, be a matter of inference during life. Where one or more of the effects mentioned above as having been noticed in cases of this kind, are present; when the pulse is small and weak; when the first sound of the heart is

fluids, and the impulse weak; when the extent of dulness on percussion is increased; and when these phenomena occur in a fat person, it may be inferred that the heart is too fat.¹ But, on the other hand, it must not be overlooked that these symptoms and signs may be found in cases of fatty degeneration of the walls of the heart, in cases where the amount of fat-tissue is but moderate. Nay, more, as already stated, both conditions are often present in the same heart, thus rendering distinctive diagnosis impossible. It is said that the presence of water in the pericardium may be confounded with the presence of fat upon the heart; but the history and general features of the case in the former condition should be sufficient to prevent all difficulty in the diagnosis. See PERICARDIUM, Diseases of.

TREATMENT.—The treatment of fatty accumulation on the heart is so intimately associated with the subject of the formation of fat in general, that this point can be discussed with more advantage in its wider relations (see OBEISITY). Whilst the treatment directed to this point is being carried out, we can do little more for the heart itself than aim at giving strength to the portion of its texture still available for duty—by tonics, steel, quinine, phosphorus, &c., secondly, by lightening as far as possible the work which the heart has to do, and thirdly, by attending to the excreting organs, so as to prevent congestion there, and consequently embarrassment to the weak heart. R. QUAIN, M.D.

HEART, Fibroid Disease of.—SYNON.: Chronic Myocarditis.

DEFINITION.—A morbid condition in which the muscular fibres of a portion of the walls of the heart are replaced by fibroid tissue.

ÆTIOLOGY.—Fibroid disease of the heart is met with most frequently in middle-aged male subjects. The disease is supposed to be occasionally but an extension between the muscular bundles of a chronic process that has commenced with endocarditis or pericarditis. The cause of this, which is generally rheumatism, is then regarded as the cause of the fibroid growth; but in reality it is more probable that in such cases the serous inflammation is the result, and not the cause, of the fibroid change. Fibrosis is sometimes the consequence of acute interstitial myocarditis. In a considerable number of cases of fibroid disease, and in most of the cases of so-called 'fibrinous deposit,' the change is probably syphilitic in its nature. In other instances it appears to be senile, and to be associated with degenerative changes in the vessels, or

chronic disease of the kidneys. Increase of fibrous tissue in the myocardium may also be the result of prolonged moderate congestion of the coronary veins. Very frequently no evident cause of the disease can be discovered.

ANATOMICAL CHARACTERS.—Our knowledge of the pathology of this disease is in a great measure due to the remarkable number of cases that have been described in the *Transactions of the Pathological Society*, the first specimen of which was presented by Dr. QUAIN in the year 1850. Fibroid disease of the heart occurs most frequently in the walls of the ventricles. It is met with under several different forms. In rare instances, which are best described as cases of *connective-tissue hypertrophy* of the heart, there is an uniform increase of fibrous tissue between the muscular fibres throughout the whole organ (see HEART, Connective-Tissue Hypertrophy of). In other instances, the disease appears as a local thickening of the connective tissue underneath an opacity of the endocardium or of the pericardium, whence septa run outwards or inwards between the muscular bundles. Most frequently, however, it presents the appearance of a *fibroid patch*, generally situated near the apex of the heart, replacing the muscular substance throughout its whole thickness, and over a greater or less extent of surface, even to as much as a considerable portion of one ventricle, and consisting of dense, firm, inelastic, greyish-white fibrous tissue. Smaller patches, nodules, scars and streaks may be found in the deeper parts of the myocardium. The apices of the papillary muscles, again, may become fibroid, especially in chronic valvular disease. Polypoid tumours, composed of fibrous tissue, have been met with on the endocardial surface of the heart, that is, projecting into one of the cavities; more especially into the left auricle. Possibly the detachment of such a polypus may be one mode of origin of the 'fibrinous balls' or 'concretions' occasionally found lying free in the auricular cavities. Fibroid and 'fibrinous' formations due to syphilis are described in the article HEART, Syphilitic Disease of.

Microscopically, fibroid disease of the myocardium presents a concomitant increase of the connective-tissue elements, and decrease by atrophy of the muscular fibres. Occasionally, in an early stage, as well as at the margins of the older patches, round and spindle-shaped cells and bundles of young fibrille have been observed. The latter increase in size and in number, press upon the intervening muscular fibres, and finally unite and form bands or patches of ordinary fibroid tissue. Meanwhile, the muscular fibres gradually become attenuated, granular, or fatty; and at last they disappear by absorption, or patches of them may be imprisoned within the fibroid growth.

The effects upon the heart of fibroid changes in its walls vary with their situation and extent. If a large portion of the wall of one cavity is fibrotic, irregular patchy dilatation of the chamber ensues. Localised fibrosis, especially if it commences beneath the endocardium, gives rise to aneurism of the heart, by the yielding of the diseased area to the intra-ventricular pressure (see HEART, Aneurism of). Deeper

¹ Dr. Henry Kennedy, of Dublin, in a recently published special monograph on *Fatty Heart*, states that the points upon which the diagnosis of fatty growth on the heart mainly turn are the following:—First, a large full pulse, beating at the natural standard of frequency; secondly, evidence derived from percussion of the heart's dulness being more extended than natural; thirdly, the possible presence of a soft systolic murmur over the aortic orifice, occupying the first sound of the heart only, and leaving the second normal; and, lastly, the condition of the individual as to his being fat or otherwise (p. 89). The present writer hesitates to agree with Dr. Kennedy as to the condition of the pulse generally, and certainly this description will not apply in the case of those persons of small frame, with small arteries, who often become obese and present symptoms of fat-heart after the middle period of life.

or more limited patches or lines of cirrhosis cause irregularity or puckering of the cardiac walls, and valvular inefficiency may result from this, or from fibrosis and functional disturbance of the papillary muscles. Lastly, fibroid disease occasionally involves the conus arteriosus in an annular form, giving rise to constriction and the formation of so-called 'cardiac stenosis.'

SYMPTOMS.—The symptoms of fibroid disease of the heart vary greatly in different instances, according to the extent, situation, and other conditions of the growth. When the fibrosis is very limited, few symptoms can be expected to be present. In the majority of cases in which a considerable portion of the cardiac wall has been found diseased, the symptoms have been described as those of 'ordinary heart-disease'; namely, dyspnoea on exertion; præcordial pain or distress; occasional palpitation, small, weak, or irregular pulse; dropsy, and visceral complications. As a rule, no endocardial murmur has been present; but fibrosis of the papillary muscles may sometimes give rise to the signs of incompetence of the auriculo-ventricular valves. The symptoms of cardiac aneurism and of syphilitic disease of the heart, as well as those of connective-tissue hypertrophy, are elsewhere described.

COURSE AND TERMINATIONS.—The course of fibroid disease of the heart is generally chronic, although urgent symptoms are sometimes observed a short time only before death. Attacks of pain, palpitation, and dyspnoea may occur and subside long previous to the last fatal illness. The development of cardiac aneurism, and its possible terminations, will modify the course of the disease. Sudden death may occur, with or without previous cardiac symptoms, and must be regarded as a special mode of termination of fibroid disease of the heart. Otherwise the cases generally end by pulmonary complications, dropsy, and exhaustion.

DIAGNOSIS.—Fibroid disease of the myocardium has to be diagnosed from chronic valvular disease; from enlargement due to extracardiac causes, such as renal disease, gout, or emphysema; and from fatty degeneration. Under all circumstances, an accurate diagnosis is extremely difficult, if not impossible. The presence of a murmur does not exclude fibrosis, as the valves may become secondarily involved, and valvular disease is not always attended by a murmur. The other cardiac lesions mentioned must be excluded in the ordinary way.

PROGNOSIS.—When fibroid disease of the heart is attended with symptoms sufficient to establish a diagnosis, the prognosis is unfavourable as regards life, although it may not be immediately so.

TREATMENT.—This consists in relieving and supporting the heart by every possible means, especially by rest and cardiac stimulants, such as alcohol and ether. Iodide of potassium may be given with benefit in some cases, especially if there be a history of syphilis. Digitalis will have to be administered with great circumspection.

J. MITCHELL BRUCE.

HEART, Functional Disorders of.

DEFINITION.—A disturbance in the functions of

the heart, with or without pain; having origin in causes other than inflammation, or structural changes in the heart itself; and for the most part paroxysmal in character.

This definition comprises various disorders in the dynamical functions and sensibility of the heart, from the slightest disturbance of only momentary duration, to urgent symptoms of considerable persistence.

ÆTIOLOGY.—The frequency of the occurrence of functional disorders of the heart, and the similarity of many of the symptoms exhibited to those met with in organic diseases, as well as the fact that these functional disorders may co-exist with organic disease, thus greatly exaggerating the apparent gravity of the latter, render it important to accurately determine how much of the disturbance may be due to the one or to the other of these causes.

To estimate the *immediate* or *proximate* cause of functional disturbance of the heart, regard must be had to its structure; and how this is nourished, and its motions regulated. For adequate and equable dynamical movement, the primary requirement is a healthy development of muscular structure. Weak muscular fibre, apart from degenerations by disease, becomes a predisposing cause of feeble and irregular action. But as the regular recurrence of the muscular contraction and expansion must, moreover, be ascribed to the agency of the cardiac ganglia, the vagus nerve, and the nerves and ganglia of the sympathetic system, all nourished and excited by the blood, any abnormal conditions of these have also their effect. Interference with the functions of these several nerves may so modify the action of the heart as to cause deficiencies of power of every variety and extent, giving rise to illustrations of abnormal contractility and irritability, which the heart exhibits in common with all other muscles. But the heart further possesses the distinguishing feature of rhythmical action. There are cogent grounds for the belief that this is not only due to the intrinsic ganglionic system of nerves; but, as errors of rhythm are certainly induced by such causes as improper diet, dyspepsia, the presence of worms, constipation, injuries or deformities of the chest, and diseases of the lungs, there can be no doubt that the heart is also liable to reflex irritation of the pneumogastric and sympathetic nerves. The rhythmical action is also shown by experiment to be dependent on the blood, whether venous or arterial; for without a supply of blood rhythmical action ceases. The healthy action of the heart, and the controlling energy of its nerves, greatly, if not entirely, depend on the supply of healthy blood; and any failure of the supply, whether in quantity or quality, shows itself by disturbance in the functions of the heart. Moreover, the muscular substance of the heart itself is nourished by the blood circulating in the coronary arteries, and thus becomes susceptible to the quality and condition of the blood so distributed; hence a blood too rich in fibrin or red globules, and thereby inducing plethora, frequently causes over-action of the heart and palpitation, whilst in anaemia a deficient amount of blood induces a weak and often excited and irregular action. The predisposing causes, in such

tion to those already named, may, therefore, be classed thus:—(1) Those conditions acting through or upon the nervous system, such as the general exhaustion of the nervous system, all forms of reflex irritation, venereal excesses, vain longings, purposeless occupations and amusements, protracted mental exercise, abstinence from adequate repose, &c. (2) Those conditions acting upon the general blood-supply of the body, and consequently affecting the special blood-supply of the heart, such as the torpid and plethoric states of gross feeders, deprived states caused by bad and deficient diet, and all forms of blood-disorder, as anaemia, gout, scurvy, &c. To these must be added the special temperament and personal peculiarities of the individual, a congenital or superimposed want of vigour, general debility, deformities of the ribs and spinal column, a small weak heart, uterine irritation, hysteria, adynamic fevers, and the special sanitary influences under which the individual is placed. Amongst the immediately exciting causes may be named mental shock or distress, protracted and unusual physical exertion; various articles of diet, as tea, coffee, &c.; tobacco in excess; in any medicines, as aconite and digitalis; as also prolonged abstinence, exposure to cold, and notably blows on the epigastrium.

SYMPTOMS.—A paroxysmal attack of a functionally increased impulse is often accompanied by a series of nervous sensations—such as a feeling of choking, at times amounting to a true *globus hystericus*; flushing of the face; heat and pain of the head, with a sensation of a whizzing or rushing upwards of the sounds of the heart, dimness of vision, with photophobia; and a tendency to syncope, and to clammey perspirations with cold shivering. The voluntary muscles may refuse to act, so that the gait becomes tottering, or the patient grasps adjacent objects to steady himself, yet there is neither palsy nor vertigo. The respiration, though not generally embarrassed, may become irregular and oppressed, presenting the phenomena of a short inspiration with a prolonged expiration, but if the paroxysms have been induced by a congested state of the right heart from using undue exertion, independently of any frequency of cardiac impulse, the breathing may be accelerated and accompanied with dyspnoea, or even apnoea, and a short dry cough. Illustrations of this class of symptoms often occur in those of sanguine and nervous temperaments; and may be the result of violent and too protracted exercise, of emotional excitements, or of the over-indulgence in stimulants or food when associated with lives of idleness and inactivity. Should the increased impulse be associated with rhythmical disturbance, there is for the most part consciousness of the existence of such states, more especially on the first ingress of the attack, so that it becomes a source of much anxiety and even of terror, inducing the self-conviction of the existence of organic disease. The head-symptoms also become more marked, and associated with local pains and *tinnitus aurium*; whilst the breathing is marked by sighing, and often becomes lessened in frequency. The irregular form of nervous palpitating heart is often associated also with humic diseases, and with ner-

vous affections, as chorea, masturbation, &c. When such diseases as scurvy or chlorosis exist, the attacks become less paroxysmal and more persistent; there is more pectoral complication, even to dyspnoea; the headache is sometimes so bewildering that the mind becomes alarmed with vague apprehensions of danger, which give rise to general restlessness; the integuments over the region of the heart, as well as of the face, and even of the extremities, may become puffy and oedematous, especially in cases of extreme chlorosis, with enlargement of the thyroid gland and exophthalmos, where the morbid conditions inducing these may also possibly cause the irregular palpitation.

When functional disorder occurs with a diminished impulse, the general symptoms group themselves under anxiety and lowness of spirits, or actual despondency, with mental and bodily incapacity for exertion; flatulent dyspepsia, with cold clammy extremities, anorexia, or, may be, depraved appetite, exhaustion, with tendency to faintness, and, should irregularity of cardiac action be very marked, there may be a sensation of precordial pain. Males are more subject to this form of functional disorder than females, and it chiefly occurs in persons having a normally small and feeble heart, or where a state of general nervous debility is superimposed.

When the distinctive feature of functional disorder is rhythmical error, and this is appreciable to the patient, the special symptom is that of extreme anxiety, even to the fear of impending death; occasionally a single intermission is so prolonged as to induce the impression that escape has only occurred by a miracle. These alarms often induce a palpitation not belonging to the rhythmical disorder. But if the rhythmical error be associated with a deficiency of systolic force, temporary paralysis of the heart's action or syncope may be induced, and in some extreme cases the functions may be weakened even to extinction. Such forms of disorder occur in those having normal but weak hearts, in the dyspeptic in the gouty, especially if an attack is impending, and in those whose habits and occupations involve exhaustion of the nervous system. They are a characteristic of old age, but may be sympathetically induced in the young; and may be observed in the course of many diseases such as tuberculosis, rheumatism, liver-affections, or when malignant disease is making its ravages.

Precordial pain is by no means an unusual symptom accompanying functional affections of the heart, it may aggravate the urgency of these disorders, yet appears to be little influenced by them. The pain does not march *pari passu* with the irregularity or strength of the impulse. The pain may be persistent, while the associated disease may be paroxysmal; and in this respect it differs from *precordial anxiety*, which is essentially paroxysmal, and acquires urgency from the symptoms with which it may be associated.

PHYSICAL SIGNS.—The physical signs referring to the cardiac action may be conveniently separated into the following groups, although in practice they will be found mingled or associated

with each other:—(1) Increased or diminished *impulse*, connected or unconnected with increased rapidity or rhythmical irregularity; (2) *rhythmical disturbance*, with intermissions, the impulse being normal or diminished; (3) increased or diminished *frequency*, the rhythm and force being normal.

(1) The cases in which an increased impulse is the distinctive feature of the heart's disturbance present many varieties, chiefly referable to force and regularity; but to the simple forms of increased and accelerated impulse there is so very frequently added rhythmical disturbance, that this complication is perhaps the one most usually occurring. The rhythmical disturbance may occur both in the force and the rapidity of the systolic contractions, or it may result in true intermissions, or occasionally the irregularities thus induced may be so great as to defy definite appreciation, save as a tumultuous whole. On palpation, the impulse, abrupt in stroke, presents the characteristic of a sudden bound, now strong, now failing, sometimes so rapid as to communicate the impression of a fremitus or agitation, then a pause, or true intermission followed by hurry, or more evident irregularity. On auscultation, the sounds are more difficult of appreciation than in simple palpitation; they are loud and clear, and sometimes so exaggerated and pronounced as to be audible both in the mammary and epigastric regions. But whether the exaggerations of sound and impulse be more or less, they will be found to act in unison with each other, the impulse and sounds increase together and diminish together. When there is an unusual amount of irregular functional excitement in systole, there may be occasionally heard, as a passing not permanent occurrence, a reduplication of the second sound, very rarely of the first; and usually the first portion of the divided or cleft sound is the most accentuated. This reduplication, though it may be met with in active inflammatory diseases, is chiefly the concomitant of functional disorders of the nervous heart only, and it rarely or never occurs in chronic diseases of the heart. The pulse is generally sharp and jerking; it does not always beat in unison with the systole of the heart; if there be plethora, it has a force and fullness not otherwise observable; and if there exist congestion of the right ventricle, it becomes contracted and diminished in force.

In cases where the impulse is diminished in effort, the special characters are somewhat negative; the impulse and sounds being feeble, but otherwise normal, unless the systole be excited by mental shock or any undue bodily exertion, when irregularity and increase of impulse, with some slight sharpness of the sounds, take place. The first sound may suggest, rather than have, a sharp ringing tone; while the second is prolonged.

(2) With respect to errors in *rhythmical action*, separately considered, it must here be noted that the chief and characteristic errors may be classified under the distinct heads of irregularity and intermission. Irregularity may be in the force or in the frequency of one or more beats, and presents the many varieties which a want of normal uniformity may suggest; the minute and

particular enumeration of these is rather satisfying to curiosity than instructive. It is sufficient to say that every variety of irregular frequency may occur; while, with certain beats, force may be increased or diminished. Sometimes there appears to be a kind of order in rhythmical disorders, that is, short series of varying irregularities may regularly succeed each other; there may be a fluttering or trembling, or that vibratory or vermicular motion to which the term 'thrill' has been given. True intermission is not so frequent as irregularity; but when intermission does occur, it is generally associated with irregularity. These disturbances may be only momentary or of long duration, slight or considerable; but, however this may be, their character is determined by the irregularity of the systole, or the prolonging of the period of intermission.

The physical examination of this form of functional disorder shows no marked peculiarities, excepting those of systolic irregularity. To the ear is revealed irregularity in the recurrence and duration of the sounds, from the slightest appreciable pause to the most rapid and confused trembling, with very manifest alterations in tone and pitch. The sounds generally are intensified, the first sound being sometimes heightened to the extent of a sharp knock; whilst the second, save in intensity, is not materially altered. In extreme cases there may be so much ventricular irregularity as to induce in place of sounds an ill-defined fremitus, and so much force as to produce a metallic ringing, with a rubbing murmur on the systole. Thus the impulse of the heart, which in health is rarely appreciable, and its friction never, respectively become so to the touch and to the ear; and the abnormal sounds may exist to such an extent as to entirely obscure the first sound.

Occasionally there is met with an appreciable rhythmical disturbance in the pulse, which is not found to exist in the heart—*false intermissions*. The heart only indicates irregularity of power; and as there is occasional failure of force in the already weak systolic contractions, the impulse is not communicated to the artery at the wrist. These false intermissions accompanying irregularity most frequently occur when the heart is oppressed by stasis in the neighbouring viscera, or is excited by injurious articles of diet, as tea, or by the use of tobacco, &c. The sensation communicated to the patient is that of a disagreeable flutter or 'tumbling over' of the heart, which tends to alarm, although habit may to a certain extent ameliorate the terror.

Rhythmical irregularity occasionally appears as a normal condition, having a life-long existence. Some cases are marked by an extension of the pause, with unsteadiness of the systolic impulse; others by its apparent extinction, so that there exists a rapidity of beats defying all analysis. There is in these cases usually a small weak heart, with systolic impulse devoid of energy. Both these classes of cases present the remarkable feature of losing much of their distinctive irregularity when under the influence of a febrile attack; the slow pulse becomes quicker and more steady, the rapid one less frequent and more distinct; but the feeling is, nevertheless,

not so comfortable as when the heart's action is in its state of normal irregularity.

(5) *Functional disorder* occasionally assumes the form of either increased or of diminished frequency, while the force and rhythm remain normal. Each of these conditions may be congenital and proper to the individual, or may be the result of abnormal influences. The functionally fast heart is generally induced by other diseases, as fever, diabetes, tuberculosis, &c., and is indicative of injury to normal innervation. The slow and drawing beat is generally met with where the nerve-power is healthy, but the heart itself is weak or fatty; or there is a perverted innervation under the influence of digitalis, aconite, or injury to the ganglionic system—a blow in the epigastrium offering a familiar example.

Hæmic murmurs are frequently heard in functional disorders of the heart, and more especially in those cases of hæmic disorder where the systolic impulse is increased, with rhythmical irregularity. These murmurs have the special characters usually attached to such sounds. They are systolic, basic, and chiefly heard in the præcordial region, with conduction in the course of the great vessels. There is no apex-murmur; but at the apex, synchronously with the murmur, the first sound is clearly defined, with a metallic ringing sound. The tone of these murmurs is musical, cooling, soft, of low pitch; the seat is in the aortic valves, and, as a rule, they are always accompanied with palpitation: this palpitation may be persistent, while the murmurs are not so. It is remarkable how large may be the amounts of blood drained from the system, and the frequency of the discharges, provided there be no diseased condition of the blood itself, without inducing the presence of a murmur. But under these circumstances, though there be no murmur, the first sound is usually flapping in character, and the second ringing in tone. The murmurs in chlorosis and spæmia, and, when they occur, in lechorrhæmia and leukæmia, have their seat for the most part in the pulmonary valves, and are not traceable in the course of the larger arteries; they are also generally associated with the venous hum to be heard in the jugular veins.

COMPLICATIONS AND SHOCKS.—The several functional disorders of the heart are often complicated with other diseases—many external to the heart, and some of the heart itself. The more prominent of the former are disorders of the nervous system and of the blood. Many of these have been already referred to. For the most part, those associated with a perverted innervation are examples of irritability, and exhibit rhythmical disorder, with pain. Hæmic diseases induce the simpler forms of palpitation; anæmia, gout, and dyspepsia induce palpitation with rhythmical disorder; spæmia and chlorosis induce all these disorders, with murmurs superadded. The diseases of the heart with which functional symptoms of disorder are often found complicated are mainly degenerations of the walls, or valvular diseases. In all these cases the amount and urgency of the functional heart-disease is no indication of the urgency of the disease with which it may be complicated.

Are there any distinct morbid states or other sequelæ traceable to functional disorder of the heart? This may be a difficult question to answer dogmatically. Doubtless frequent and prolonged attacks of functional disorder are seen to occur without inducing any such. On the other hand the long continuance of functional disorder is often marked by a depreciation of mental and bodily vigour. More specific organic changes are generally found to be due to some one or other of the diseases with which the functional disorder has been in its course associated.

DIAGNOSIS.—In order to make a correct diagnosis, the first consideration is to ascertain the entire absence of organic disease; and, if it be present, whether it is adequate to cause the full amount of the symptoms exhibited. Supposing this to have been done, if the agitation of the heart is not only excessive, sudden, and apparently increased in strength, even to violence, but has often the features of spasm rather than the calmness of rhythmical order; while the sounds are *pari passu* increased in sharpness and intensity, and diffused over a larger area than is proper to them, and the pulse does not partake of the simulated force of the heart—the presence of an excited functional impulse may be assumed. The concurrence of some symptoms usually associated with organic disease, as dyspnoea or even apnoea and œdema, may, as has been shown, be due to the presence of chlorosis. So also where there is a deficient impulse, if the heart have its normal position and dimensions; if the sounds though weak be natural in tone and quality, in the absence of any abnormal physical disease, it may be concluded the cause is functional only. The same may be said of rhythmical irregularities. When any of these symptoms are associated with hæmic murmurs, the character of the murmur, its seat, and its persistency must be considered in connection with the absence or the presence of hæmic diseases. The symptoms of each of these several forms of functional disorder have been so fully described that there is no need to repeat them here. It must, however, be always borne in mind that the absence of the physical signs of disease is not always conclusive of there being no structural lesion, for there may be lesions, and important ones too, that do not yield evidence of their existence. The occurrence of the secondary changes, the immediate result of various congestions, is often an indication that the heart-symptoms are due to the presence of organic disease: still it is not always so, for congestions of the lungs and liver, and œdema, may be the consequence of spæmia or of other morbid conditions of the blood. Hence, when these are present, the symptoms exhibited by a disordered heart may not be due to structural disease; and the same may be said of the effects of muscular exercise and of position, for either or both of these may distress if there be present any anæmic condition or an intercostal neuralgia. Nor, on the other hand, does the occasional subsidence of urgent symptoms, so frequently the case in functional disorder, absolutely affirm the conclusion that there is no organic disease: for occasionally in the latter the normal rhythm and force of the heart may

resort themselves; but then in these cases there remain the other characteristics of the organic affection. Frequent examination and an accomplished experience will generally lead to a just diagnosis.

Prognosis.—The prognosis of functional disorders of the heart, for the most part, is favourable. Where there are baneful constitutional tendencies, or complications with other diseases, the prognosis must not, however, be always so considered. In the leucopneumatic temperament the paroxysms may be severe and abiding, and generally distressing to the nervous system. If the symptoms be so urgent as to distend the right heart, the liver may become loaded, and dropsy may ensue. In this temperament mental shocks may induce palpitation, irregularity, and syncope, whence may ensue not only permanent heart-affection and eventually disease, but even immediate death. When functional disorder is the concomitant of scurvy or anæmia, the prognosis is not always favourable. Still in the young and middle-aged there is good chance of ultimate recovery, for if these diseases be subdued the functional disorder subsides. When occurring in the aged, or in those having a constitutional tendency to hypochondriasis, or when associated with organic diseases, or excited by inflammations of the endocardium, a less favourable prognosis must be given. Functional rhythmical irregularity, for the most part, does not indicate danger, but it may do so if associated with some obscure structural lesion. Nevertheless, cases of simple functional disorder, so severe as apparently to indicate an immediately fatal termination, prove, for the most part, manageable, and result in a restoration to health. The freedom of the heart from all agitation and other indications of disease, before and after an attack, is due to its being a normal and uninjured organ; and though liable during an attack to the morbid influences of spasms and congestive loading, it still may be a healthy organ. This holds whether the paroxysms be short or prolonged, occurring rarely, or frequently recurring. They are distressing but not dangerous.

Treatment. Treatment should have reference primarily to the paroxysm, and then to its exciting causes, the indications being, first, the mitigation of the symptoms; and, secondly, the prevention of their recurrence.

Treatment of the paroxysms.—Towards the former, it should be ascertained, where possible, whether the attack be essentially due to irritability in the heart itself, or whether it have its origin in some co-existing eccentric cause. The constitutional tendency and the exciting causes should be well considered; for the treatment of apparently similar attacks under the widely-opposite causes of a plethora or an anæmia must be varied accordingly. Slight cases subside of themselves; but in more persistent attacks, for the most part, relief is obtained by warm carminatives or stimulants, or by antispasmodics, as ammonia, camphor, ether, asafoetida, musk, valerian, or sambal. Where irritability of the heart itself is the cause of the attack, it is generally best met by sedatives, as opium, hyocyamus, hydrocyanic acid,

and in some cases digitalis. If the attack be due to derangement of the stomach, so from the presence of the gastric acids, an alkali may be useful. In extreme cases, and where head-symptoms supervene, the extraction of a small quantity of blood by leeches or venæsection may be useful. The mental or moral treatment is of the greatest moment. A confident and cheering prognosis conduces to recovery, and prevents the nervousness which exhausts and tends to prolong the disorder.

Treatment between the paroxysms.—The paroxysm being allayed, it is then well to examine carefully into the state of health, so as to ascertain if there be any of those disordered conditions which may probably have been its exciting cause. Dyspepsia is to be relieved, the liver is to be set right, the uterine functions are to be restored to regularity, loaded bowels relieved, plethora subdued; spasmæmia and chlorosis strengthened into health, exhaustion compensated for, and debility counteracted; and the over-worked must seek renovation in travel and cheerful recreation. In persons prone to these disorders many precautions should be observed. The young and the plethoric must avoid extremes of diet and exercise; the food should be moderate in quantity and unstimulating in quality; and exercise should be unfatiguing, and chiefly taken in the open air. Hot and ill-ventilated rooms, and the postponement of sleep by late hours, should be especially avoided. A careful mental discipline should be observed; and this must be sought in a healthy exercise of the brain, and restraining, by a well-ordered intellectual culture, the tendency to vain imaginings and emotional passions. The constitutionally nervous and irritable in mind must sedulously avoid exciting situations, as well as exhaustion by overwork. The sluggish and hypochondriacal must resist the temptations to inaction, seeking to overcome these tendencies by exercise; by cold bathing, more especially by means of the shower-bath; and, if the bowels be confined, by the judicious use of aperients. As all the varieties of functional disorder of the heart are peculiarly under the influence of a morbid will, it becomes of the first importance that the medical attendant should generally encourage and cheer; and as soon as careful investigation has satisfied the requirements of a just prognosis, further investigations by the stethoscope should be avoided. Empirical investigations tend to prolong the disordered action, and perhaps so to impress the imagination as to forbid recovery.

THOMAS SHAPPEL.

HEART, Hemorrhage into the Walls of.—**SYNON.** Cardiac Apoplexy.

DEFINITION.—Extravasation of blood into the substance of the heart.

ÆTIOLOGY AND PATHOLOGY.—Blood is extravasated into the substance of the heart in various pathological conditions, but as these are described under their respective headings, it will not be necessary in this place to do more than refer to them.

Rupture of the heart is the most frequent origin of hemorrhage into the walls of the organ.

The blood in these cases may be derived from the cavity of the ventricle, and forced between the muscular fibres at each contraction. More rarely, a partial rupture of the wall may occur, unconnected with the cavities, and hæmorrhage takes place into the seat of the lesion from one of the coronary vessels or their branches, constituting what has been called *coronary apoplexy*. In both classes *fatty degeneration* is generally the cause of the rupture.

The formation of false consecutive *aneurism of the heart* may be attended with hæmorrhage into the walls; an abscess, blood-cyst, hydatid-cyst, or gramma having burst or made its way into one of the cavities.

The *coronary arteries* may be the source of the hæmorrhage; for instance, in rupture of coronary aneurism; in cases of cancerous ulceration of their walls; and in embolism or thrombosis of their lumen, leading to infarction.

Echymosis of the heart is a form of hæmorrhage belonging to a different category. It is generally met with in association with parenchymatous degeneration of the heart, for example in the acute specific fevers; with that form of fatty degeneration which is produced by certain poisons, such as phosphorus and arsenic, and with other pathological states in which ecchymoses occur in the viscera generally, as in purpura and scurvy, and especially in cardiac and pulmonary disease.

In cases of non-fatal hæmorrhage into the walls of the heart, the blood undergoes the changes usual in extravasations, and gives rise to the collections of pigment-particles which are sometimes found between and upon the muscular fibres, to blood-cysts, or to collections of puriform matter.

Hæmorrhage into the myocardium possesses no special clinical relations.

J. MITCHELL BRUCE.

HEART, Hydatid-Disease of.—A considerable number of cases have been recorded in which hydatids, in the wider sense of the term, have been found in the human heart. According to Dr. Cobbold, 3·6 per cent. of all cases of hydatids in man occur in this situation.

ANATOMICAL CHARACTER.—Hydatid-cysts of the heart are either simple or multiple, the latter being the more common of the two forms. They are situated in the myocardium of either side of the heart; but tend naturally by enlargement to project either into the pericardial sac or into one of the cardiac cavities, in the form of a prominent cystic tumour. In this condition they have generally been found *post mortem*; but it is probable that in other cases the parasite may undergo degenerative changes in the heart, as in other organs, without its existence being suspected during life or discovered after death. In other instances, the hydatids rupture or are dislodged from their seat in the cardiac wall—either inwards or outwards, or in both directions at once. In the first event, the parasite or its contents or fragments become impacted in the cardiac cavities or orifices, or give rise to embolism of the great vessels or of a distant branch. Rupture of a cyst into the pericardial sac causes pericarditis; and rupture both inter-

nally and externally has given rise to hæmopericardium.

Hydatids of the heart are frequently associated with the same disease in other viscera. The appearance and structure of the entozoon do not require to be described here. See HYDATIDS.

Symptoms.—In several cases of this disease, the subjects have died suddenly during exertion, or, as in a case recorded by Dr. Wilks, after a hearty meal. These persons were not known to have suffered previously from symptoms referable to the heart. In other instances, the ordinary phenomena of chronic cardiac disease were present including endocardial murmurs, but it is not certain that these were always due to the presence of the hydatids in the heart. A sudden fatal termination will be the result of internal rupture and embolism, or of hæmopericardium, as described above.

DIAGNOSIS.—Hydatid-disease of the heart does not appear to have ever been suspected during life. Cardiac symptoms and signs, or sudden death, occurring in an individual known to be suffering from hydatids of other viscera, would suggest that the heart was also affected.

TREATMENT.—The disease cannot be said to have any special interest therapeutically.

J. MITCHELL BRUCE.

HEART, Hypertrophy of.—SYNON.: Fr. *Hypertrophie du Cœur*, Ger. *Hypertrophie des Herzens*.

DEFINITION.—Hypertrophy of the heart, in a wide acceptance of the term, may be said to express an increase in the size and weight of the organ, due to an excessive development of some one of the constituent elements of its walls. In the sense in which it is generally used, however, hypertrophy of the heart signifies an excessive development of the muscular substance only.

Such hypertrophy may be regarded as a conservative process; and is not intended to include those changes in the size of the heart in which the connective and fatty tissues are in excess.

VARIETIES.—The varieties of hypertrophy of the heart were first carefully described by M. Bertin in 1811, who demonstrated that the change in hypertrophy is the result of an increase of nutrition. He described three forms, which most succeeding writers have referred to, namely:—(1) *Simple Hypertrophy*, in which the parietes of the compartments are thickened, the cavities retaining their natural dimensions; (2) *Hypertrophy with Dilatation* (*Excentric Hypertrophy*), in which the cavities are increased in capacity, while the parietes are either of natural or of augmented thickness; (3) the so-called *Concentric Hypertrophy*, or *Hypertrophy with Diminished Cavities*, in which new material was supposed to be added, chiefly in the interior of the ventricular walls. Cruveilhier and Budd pointed out that the condition called concentric hypertrophy is the result, not of hypertrophy, but of a powerful contraction of the organ suddenly arrested, as it were, by death. Budd found that the hearts of persons who had died a violent death presented this so-called concentric hypertrophy; but that such hearts became relaxed, and showed the normal size of cavities and thickness of walls, after maceration. Rokit-

tasky and Ramberger acknowledge the rarity of concentric hypertrophy, but think it does sometimes occur. It is said to have been found in the right ventricle in some cases of congenital malformations. Hypertrophy may affect only one compartment of the heart, or more than one, but the organ is seldom enlarged throughout. The ventricles are much more frequently hypertrophied than the auricles, and the left ventricle more frequently than the right; but the right auricle more frequently than the left auricle—which last shows the change very seldom.

ÆTIOLOGY AND PATHOLOGY.—The heart being a muscular organ, whatever calls forth increased frequency and force of its action induces hypertrophy of its muscular tissue. The great causes of this hypertrophy are certain obstructive conditions in the circulatory apparatus, which will be noticed in detail. But many circumstances might be enumerated as *predisposing* causes. Thus, males, from the nature of their occupations, are twice as prone to cardiac hypertrophy as females. In advanced age degenerative vascular changes are apt to induce this result.

Dr. Quain (*Lumleian Lectures*, 1872) has classified the *exciting* causes of hypertrophy under three heads:—*nervous*, *mechanical*, and *nutritive*. 1. Amongst *nervous* causes are those emotional conditions that produce frequent palpitation, and prolonged mental excitement or strain. The immoderate use of strong coffee, tea, or spirituous liquors might come under this head. 2. Amongst *mechanical* and physical causes are all those obstructive conditions to be afterwards specially examined. Violent athletic or other exercises, which notably accelerate the contractions of the heart, or produce excessive blood-pressure, may be mentioned here. It has been pointed out that great muscular exertion with the arms is specially prone to cause hypertrophy, as in the case of hammermen, &c. Prolonged working in a bent or constrained position is also mentioned as a cause. In fact, any prolonged impediment to the free action of the heart, or to the onward current of the circulation, tends to cause hypertrophy of the heart. Thus, in addition to valvular lesions, pericardial adhesion is an important cause. Diseases of the vessels, by diminishing their elasticity and increasing the friction, displacements of the heart, and deformities of the chest or spinal column, by twisting or constricting the aorta, are all causes of some obstruction to the blood-current. The heart becomes enlarged in pregnancy—but resumes its ordinary size by involution—as the womb itself does. A very important cause of cardiac hypertrophy is chronic Bright's disease. Aneurisms also sometimes induce hypertrophy, for the physical reason that the resistance encountered by a liquid flowing through a tube is increased by the presence of any abrupt dilatation and contraction of the calibre of the tube. Conditions of the lungs associated with persistent obstruction to the passage of blood through them (emphysema, asthma, phthisis, compression from hydrothorax, &c.) may induce hypertrophy of the right side of the heart. Hypertrophy also follows upon dilatation, because additional force is required to propel the larger volume of blood, apart from any valvular lesion. So more pic-

thora may tend to cause hypertrophy, which also arises upon the distension of the cardiac walls which results from myocarditis. 3. With regard to the *nutritive* causes of hypertrophy of the heart, the state of the local nutrition and the nutritive quality of the blood have both to be taken into account. Rich nitrogenous food, and the use of ferruginous medicines, will favour hypertrophic changes. With the increase of the muscular structure there is proportional enlargement of the coronary arteries, so that the hypertrophied organ has an increased blood-supply.

The most important *conditions of obstruction* connected with cardiac hypertrophy are the following:—(a) *Stenosis of the aortic valves* is a common cause of hypertrophy of the left ventricle. The opening is not only narrowed, but is also rendered more rigid, and thus increased force is necessary to propel the blood. Along with the valvular lesion there may also be, especially in advanced life, a loss of elasticity and a roughening of the inner coat of the aorta from degenerative changes conditions which increase the mechanical strain upon the left ventricle. (b) *Aortic regurgitation* often induces so great enlargement of the left ventricle, from hypertrophy and dilatation, that the heart in such cases merits the name *cor bovinum*. The back-flow of blood increases the intra-ventricular pressure, tends to dilate the cavity, and calls forth augmented efforts of ventricular contraction. (c) *Aortic aneurism* is usually instanced as a cause of cardiac hypertrophy, and we gave above the physical explanation of this result. But, as a matter of fact, many cases of aortic aneurism have been recorded not accompanied by cardiac hypertrophy, though some degree of this change is usually expected. Of course, other tumours, by pressing upon any of the great arterial trunks, may induce cardiac hypertrophy. (d) *Chronic Bright's disease* (contracted kidney) is a very important cause of left-heart hypertrophy, the hypertrophy being often of the purest type, without dilatation. This change is the result of the great increase of blood-tension produced by the resistance offered to the blood in the small arteries through the whole body, as well as in the kidneys. (e) As the result of *mitral stenosis*, the left auricle becomes somewhat thickened and dilated; and the further backward blockage of the blood produces pulmonary engorgement, and hypertrophy with dilatation of the right-heart. (f) Similar results follow the more common lesion—*mitral incompetence*. Blood regurgitates at each ventricular systole into the left auricle, which has thus to sustain the ventricular impulse in addition to the pressure from excessive fulness. Hypertrophy and dilatation of the left auricle, engorgement of the lungs, and hypertrophy with dilatation of the right-heart, are the natural consequences. Indeed, hypertrophy of the right ventricle is almost always associated with dilatation, and the double change is, in almost every case, consequent upon pulmonary obstruction, which may be caused by primary changes in the lungs themselves (see g), but is far more frequently secondary to left-heart disease (mitral lesions). (g) In *emphysema*, *fibrosis*, and *consolidated* or *compressed* conditions of the lungs, the impediment to the pulmonary circulation induces hypertrophy with

dilatation of the right ventricle. *Diseases of the pulmonary orifices* are very rare; so, too, is *tricuspid stenosis*. (4) But *tricuspid regurgitation* is common as a result of dilatation of the right ventricle; and this, in its turn, causes dilatation, usually with considerable hypertrophy, of the right auricle. General systemic venous obstruction follows upon right-heart blockage; and Huxley says that venous retardation may work backwards through the capillaries to the minute arteries, the consequent increased resistance in which may induce left-heart hypertrophy.

ANATOMICAL CHARACTERS.—The fundamental anatomical change in cardiac hypertrophy is an increase of the proper muscular tissue of the heart. There is no growth of new tissue different from the normal heart-muscle; there is simply an increase in the number of muscular fibres in all respects similar to those normally occurring in the organ. Along with the hypertrophy of the muscular tissue, there may be also more or less increase of the connective tissue between the muscular bundles; and this fibrous hyperplasia may be excessive, as Dr. Quain has pointed out, constituting a so-called 'false hypertrophy,' in which the colour of the cardiac walls varies from the natural to a light grey hue. There may be hypertrophy of only one part of the cardiac walls, abnormal thinning being found in other parts. The organ may be greatly enlarged from general dilatation, without any notable thickening of the walls; but the capacity of the chambers should always be carefully noted in estimating the degree of hypertrophy, as there may be a greatly augmented extent of wall, although its actual thickness seems normal. Simple hypertrophy is nearly always the first condition, preceding hypertrophy with dilatation. The greatest cardiac enlargements result from left-sided hypertrophy. Some examples of *cor bonum* have attained the enormous weight of 40 oz. The wall of the left ventricle may become thickened to one or even one-and-a-half inches, instead of the normal six or seven lines; and the thickest part is usually about the middle of the ventricle. The inter-ventricular septum is not so liable to hypertrophy as the rest of the ventricular parietes. The right ventricular wall may be thickened to the extent of one inch, instead of the normal two-and-a-half lines, and its greatest thickness is at its base. The columnar curve of the right ventricle is even more liable to hypertrophy than the wall. In dilatation with hypertrophy the columnar curve becomes stretched and attenuated. The substance of an hypertrophied left ventricle can generally be torn with ease, whilst that of an hypertrophied right ventricle is usually tough and leathery. The auricular walls are rarely thickened to more than twice the natural thickness, and are almost always dilated considerably if hypertrophied at all. In marked hypertrophy, the heart presents a change of configuration, becoming more globular, and having the apex tilted up. If the enlargement is mainly on the right side, the sphericity of the organ is a marked characteristic, and its long diameter has a transverse direction in the chest. Of course, other pathological conditions, as valvular lesions, or the results of endocarditis or of pericarditis, may also be present. In true hypertrophy the coronary arteries become

enlarged. There may sometimes be found accumulations of fusiform involuntary fibres, which have not developed into the higher state of striped fibres.

SYMPTOMS AND SIGNS.—Precise physical signs are all-important in establishing a diagnosis in cardiac enlargements, and it is always expedient at once to ascertain which chamber or chambers is or are affected. It must not be forgotten that simple hypertrophy may exist without producing symptoms attracting the attention of the patient, and that there is a natural tendency to some degree of cardiac hypertrophy with the advance of age. *Dyspnoea*.—In moderate hypertrophy without complication, there is usually easy and natural breathing when the patient's body and mind are at rest. But mental excitement or bodily effort at once induces more or less of temporary dyspnoea. In some cases the due expansion of the lungs may be mechanically impeded by the increased volume of the heart. In excentric hypertrophy, with dilatation, more especially when the right cavities are thus affected, pulmonary congestion and oedema are very usually present, and then marked dyspnoea is a prominent and distressing symptom. *Cough*.—In simple hypertrophy there may be an occasional dry irritating cough, and in young phlebotomic women a whooping cough may be complained of. In right-side enlargements when pulmonary obstruction and dropsical effusions supervene, cough is, in most cases, a very frequent and painful addition to the other sources of discomfort to the patient. *Hemoptysis and other hemorrhages*.—Hemoptysis from capillary engorgement is common, being generally active and sudden. Niemeyer points out that, in left-heart hypertrophy, there is often active distension, and sometimes rupture, of the branches of the bronchial arteries. In left hypertrophy, too, the cerebral arteries are especially liable to give way. In right-side enlargement with pulmonary obstruction, the blockage may influence the vessels of the liver and the portal system generally, so as to produce hæmatemesis or melæna. Epistaxis may also be due to cardiac enlargement. *Palpitation* is a common symptom in all organic diseases of the heart, and is often very marked in cardiac enlargements. The least excitement, bodily or mental, may induce a greater or less degree of this symptom. Especially in excentric hypertrophy with dilatation, most distressing paroxysms of palpitation are apt to occur from time to time. Besides bodily and mental excitement, other conditions, such as indigestion, flatulence, or an overloaded stomach, readily call forth this symptom. When there is much dilatation, the palpitation may be irregular and intermittent, and is then more particularly a very alarming symptom. *Pulse*.—In simple hypertrophy the pulse is stronger, fuller, tenser, less compressible than natural, and *dissatisfied* under the finger, the hypertrophied walls requiring more time for contraction, and contracting with greater force than normal. When dilatation relatively exceeds the hypertrophy there is diminished strength, but more fulness, and sometimes marked slowness of the pulse. In aortic obstruction with left hypertrophy the pulse is strong incompressible, small, and sustained.

In aortic regurgitation it feels as if liquid balls passed under the finger. In mitral obstruction it is frequently small and irregular. In mitral regurgitation it is irregular in size (not necessarily in rhythm). In enlargement of the right ventricle the pulse, as a rule, is small, weak, and perhaps intermittent or irregular. When atheroma of the vessels is associated with cardiac hypertrophy, the pulse is bounding. In the mere hypertrophy of old age it is full and slow, but not very incompressible. Certain cerebral symptoms ought to be mentioned in connection with the other more direct signs of cardiac hypertrophy. A feeling of fullness, or perhaps of throbbing, may be felt in the head after great muscular exertion or mental excitement. In pronounced cases there may be headache, ringing in the ears, vertigo, muscæ volitantes, and disturbing dreams. The bright and shining, or perhaps the blood-shot, condition of the eyes, is an indication of the hyperæmia of the cerebral vessels.

Hypertrophy of the Left Ventricle.—Simple hypertrophy of this portion of the heart does not usually produce much disturbance of respiration, but palpitation is a prominent symptom, and cerebral complications are, as we have seen, by far most frequent in this form of cardiac change. On inspection, the præcordium sometimes shows a bulging, more especially in young subjects, whose sternal cartilages are less resistant. Walsha says there may be some convexity of the cardiac region from the third to the seventh cartilages, and that the interspaces are rendered wider, but do not bulge. In simple hypertrophy the area of impulse may be seen to be enlarged, and to be located more to the left and lower down than normal. On palpation the apex-impulse may be felt to be greatly augmented in force, and to extend perhaps over the fourth, fifth, and sixth interspaces. When there is very great hypertrophy of the left ventricle, without pericardial adhesion or much dilatation, the apex-beat may be felt, powerful and well-defined, even in the seventh or eighth intercostal space. Dr. Walsha describes the sensation as a slow heaving, or a pushing forward as if against an obstacle. The duration of the heaving impulse is in proportion to the degree of hypertrophy. The impulse is often strong enough to visibly move the bed-clothes, and even to raise the head of the auscultator by the impact against the stethoscope. Of course a larger portion than usual of the heart's surface impinges against the chest-wall. With coexistent valvular lesions, a vibratory jarring sensation may be felt on palpation; and with pericardial adhesions the impulse may be a sort of juggling motion.

In hypertrophy with dilatation the impulse is less powerful, but is seen and felt over a wider area than in simple hypertrophy. The contractions are felt more like sharp blows or shocks, and the vibrations are conveyed to greater distances, in some cases extending to the top of the chest-wall. With great dilatation the pulse may be very slow, weak, and compressible. On percussion, the areas of both the superficial and the deep cardiac dulness are found to be increased, especially towards the left. In excessive hypertrophy with dilatation, the dulness may extend

from the upper border of the third rib down to the eighth rib, and from an inch to the right of the sternum to the anterior axillary line. Dulness may also be detected in the left back. Emphysema and possible consolidation of the lungs must be borne in mind in marking out the area of cardiac dulness. On auscultation, the systolic sound is less clear and defined than normal in simple hypertrophy, it is prolonged in proportion to the degree of hypertrophy, and is muffled in character, as the muscular sound is excessively pronounced, and obscures that of the auriculo-ventricular valves. When there is much hypertrophy, the first sound may be of a metallic character. The post-systolic silence is shortened, and the second sound is loud. When there is dilatation with hypertrophy the first sound is more audible and distinct, and the second sound is louder.

Hypertrophy of the Right Ventricle.—In enlargements of this ventricle, inspection may reveal a rounded smoothness of the epigastrium, with perhaps some bulging of the ensiform and lower left costal cartilages. The apex-beat may be seen to be very diffused, extending towards the tip of the ensiform cartilage. Facial lividity is frequently seen, and jugular pulsation may be observed when there is tricuspid regurgitation. Palpation over the lower part of the sternum detects an impulse, which feels as if immediately under the hand, and wants the heaving character of the impulse of a hypertrophied left ventricle. Epigastric pulsation is often very pronounced. The liver-pulsation in such cases may result either from venous regurgitation, or from right systolic action exerted through the diaphragm. On percussion, the inferior line of dulness is found to extend lower down and further towards the right than normal, sometimes reaching an inch or more beyond the right sternal edge. The dulness may be continuous with that of the liver. On auscultation, the first sound is more distinct than normal, and seems quite superficial. The second sound is also louder, and its reduplication is not uncommon.

Hypertrophy of the Auricles.—It is always difficult to speak very definitely of the condition of the auricles during life. They are never hypertrophied without being also dilated, and such states are uniformly connected with lesions of the auriculo-ventricular valves. Dulness due to an enlarged left auricle may extend up to the second left intercostal space; that due to an enlarged right auricle may be found in the third and fourth interspaces at the right sternal edge. Jugular pulsation may be found along with right auricular enlargement, which itself can hardly ever occur without an abnormal condition of the right ventricle.

COMPLICATIONS AND SEQUELÆ.—Simple hypertrophy of the heart may go on quietly for a long time, just balancing the obstructive influence, and giving rise to no other form of disease. But when there is dilatation as well as hypertrophy, then palpitation, dyspnoea, venous congestion, and serous effusions are the ordinary results. Diseased conditions of the arteries may occur simultaneously, or may be induced by the long-continued additional strain put upon them.

by a hypertrophied heart. Cerebral hæmorrhage often occurs in connection with an hypertrophied left ventricle, as in Bright's disease; although there are very frequently other factors, besides the mere excessive propulsive power of the heart, in the production of apoplexy. Pulmonary and general congestion and œdema are the usual attendants of mitral lesions with right-side enlargements. Pulmonary hæmorrhagic infarction (the so-called 'pulmonary apoplexy') generally results from embolism of the branches of the pulmonary artery, and takes place in connection with right-side enlargement. Sanguineous exudation in the tract of the bronchial mucous membrane may occur in left-heart hypertrophy. Persons suffering from cardiac hypertrophy are apt to be gravely affected by acute febrile diseases, because the resultant acceleration of the heart's action increases the embarrassment of the organ. Of course, hypertrophied cardiac walls are subject to the fatty degenerative changes described elsewhere. As has been alluded to already, the chief result of right-side dilatation is obstruction to the venous return. The hepatic circulation and the portal system generally are, in particular, rapidly overfilled, the whole venous system being ultimately affected. The kidneys likewise suffer. The natural results, in addition to characteristic changes in the chronically congested organs, are serous effusions into the cavity and subcutaneous areolar tissue.

DIAGNOSIS.—An extended area of dullness; displacement of the apex-beat; and a slow, heaving systolic action, with augmented force of impulse, are the chief diagnostic physical signs of cardiac hypertrophy. In young and thin people the last of these signs may seem to be present, but the accompanying conditions readily exclude hypertrophy, especially the non-extension of the cardiac dullness. An *emphysematous left lung* may mask hypertrophy when present; and *lung-consolidation* might, though only for a moment, suggest it when absent. In *pericardial effusion* the triangular shape of the area of dullness, with the apex of the triangle upwards, is a distinctive feature; there would, moreover, be the history of an acute disease, with lancinating pain, dyspnoea or suffocative sensations, and other symptoms not found in mere enlargement of the heart. *Pleuritic effusion* or *aneurism* would be still more readily discriminated. The differential diagnosis between left-heart and right-heart enlargements has been sufficiently discussed in speaking of the symptoms and signs. *Dilatation* as distinguished from hypertrophy, is characterised by the feebleness and diffuseness of the apex-beat, which may even be quite imperceptible; by the great irregularity and intermittency of the heart's action; and by the general signs and symptoms of a feeble circulation.

PROGNOSIS.—Simple, uncomplicated hypertrophy, as in the young, and in athletes, is not incompatible with long life, if the cause be removed in time. According to the extent and degree of complication, whether in the form of valvular lesions or co-existent pulmonary disease, the prognosis will be unfavourable. When the cardiac change is itself producing secondary lesions, as degenerations of the arterial coats, when dilatation is advancing, and when there is

Bright's disease, the prognosis becomes very unfavourable.

TREATMENT.—Hypertrophy being in itself a conservative change, protective from worse results, the primary object is to remove, if possible, the cause of the hypertrophy. To aim merely at reducing the hypertrophy, irrespective of its cause, as by lowering the nutrition, would gravely favour the worse evil of dilatation. General therapeutic principles, and the modifying conditions accompanying the hypertrophy, must therefore be carefully attended to. All mental and bodily exertion which excites the circulation must be scrupulously avoided. All alcoholic stimulants should be interdicted, and no more wine allowed than such as may seem to benefit digestion. The diet should be carefully selected, nitrogenous food being generally necessary. The digestive organs must be sedulously looked after, not only because good nutrition is very important, but also because flatulence and dyspepsia directly embarrass the heart's action. Mild saline and aloetic aperients should be given. Diuretics will be necessary if there is a tendency to dropsy, and in all cases great attention must be paid to the removal of congestion when it affects important organs, and the restoration of their functions when affected, more especially of the liver and the kidneys. When there is great excess of cardiac action, direct cardiac sedatives, as digitalis, hydrocyanic acid, conium, and belladonna, are called for. When there is dilatation and feebleness of texture with the hypertrophy, iron and digitalis are the chief remedial drugs.

J. R. WARDLE.

HEART, Inflammation of.—Inflammation of the heart may affect either the lining membrane, or the substance or walls of the organ, and the subject will be best discussed under the separate heads of *Endocarditis* and *Myocarditis*. Inflammation of the investing membrane of the heart is described in the article **PERICARDIUM, Diseases of**.

1. Endocarditis. **SYNON.**: Fr *Endocardite*; Ger *Endocarditis*.

DEFINITION.—Inflammation of the lining membrane of the heart.

Inflammation of the endocardium may be either acute or chronic. The acute form alone will be discussed here; chronic endocarditis being referred to under the head of **HEART, Valves of, Diseases of**.

ÆTIOLOGY.—Endocarditis generally occurs in association with acute rheumatism; less frequently with the other acute specific febrile diseases, such as scarlet fever, measles, erysipelas, pyæmia and septicæmia—including puerperal fever, and much more rarely with typhoid fever and variola. Occasionally it is observed in the course of pregnancy, and after parturition; in acute and chronic Bright's disease; and in syphilis. Wounds and other injuries of the heart, such as rupture of the valves, may also lead to endocarditis; and local inflammation of the endocardium is frequently the result of the unnatural contact of one part of it with another during the cardiac revolution, as, for example, by growths from the walls or valves, or by unnatural blood-

currents. It also occurs in chorea, perhaps from the lust of the causes just enumerated.

Age is an important predisposing factor in the etiology of acute endocarditis, the occurrence of which as a complication of acute rheumatism is certainly most frequent in young subjects, and declines as age advances. Women are also more subject to rheumatic endocarditis than men.

The localisation of the endocardial inflammation appears to be determined chiefly by pressure and tension, rather than by any peculiarity of the membrane itself, or of the blood in contact with it. Thus the left ventricle is almost the sole seat of the disease in the adult, and the right ventricle in the fetus, whilst endocarditis is rarely seen beyond the boundaries of the valves, that is, the parts most subjected to strain. In the same way, chronic endocarditis is usually due to increased pressure within the heart, as in chronic Bright's disease, and in conditions that entail prolonged severe strain upon the valves during exertion. A similar cause is at work in pregnancy.

In a certain number of instances of the *ulcerative* form of endocarditis, the origin of the disease has been traced in connection with the presence of an ulcerating surface or foul wound in some part of the body, most frequently in the female genital organs *post partum*.

ANATOMICAL CHANGES.—Inflammation of the endocardium affects chiefly the valves and the chordæ tendineæ, and especially the lines of contact or the surfaces of the valves exposed to the force of the blood-current. The endocardium of these parts at first appears slightly swollen, velvety, soft, and of various shades of red, whilst the lines or points of contact of the valves present warty enlargements of a similar character, which are known as 'vegetations.' As the process advances, the inflamed areas become more opaque and firm, and a fibrous deposit is entangled with their surface. When the endocarditis has gone thus far, resolution is probably rare, and the most common result is what is known as 'chronic valvular disease,' that is, that the affected parts are left opaque, puckered, and thickened by growth of connective tissue, whilst the vegetations develop into firm fibroid or even cartilaginous-like bodies. As a consequence of these changes, the valves may become much altered in size and shape, and the osm contracted and irregular, so that the mutual adaptation of the parts is greatly disturbed. Other results of inflammation are not uncommon in the progress of endocarditis, such as adhesions between the neighbouring structures, and ossification or calcification of the altered tissues. Laceration of the valves and rupture of the chordæ tendineæ during the stage of diminished resistance, ulceration, suppuration, and the formation of aneurism are rarer events.

The microscopical appearances of inflammation of the endocardium correspond with the naked-eye characters. In the early stages, the proper tissue of the endocardium is swollen by hyperæmia, œdema, and the appearance between its fibres of a number of leucocytes, the latter rapidly multiply to form the bulk of the vegetations; and the surface presents various thicknesses of deposited fibrin, which in its turn may

become organised. The further development of the new cells into connective tissue gives rise to the opacity, thickening, and puckering of the valves, and to the formation of permanent vegetations.

The effects of these changes upon the functions of the valves and their appendages are described in the article *HEART, Valves of, Diseases of*. Particles of fibrin, and even of the vegetations are occasionally detached from the endocardium, and give rise to embolism.

In a special form of the disease, which is known as *ulcerative endocarditis*, the morbid appearances are at first not unlike those described above as characterising the early stage of the ordinary affection; but the process pursues a different course, and becomes mainly destructive in its nature. The edges or surfaces of the valves then present spots or patches of loss of substance, having an eroded appearance, and an irregular base, covered with granular matter, and fringed by vegetations. These diseased areas may advance to actual perforation, burrowing abscess, or aneurism. Microscopically examined, the patches prove to be areas of ulceration, and the granular matter of their base has been found by Virchow and others to contain organisms, which were seen at the same time in the capillaries of distant parts of the body.

SYMPTOMS.—The symptoms of endocarditis are inseparable from the symptoms of the disease with which it is associated, and the diagnosis of it is made almost entirely from the presence of physical signs. Thus fever probably precedes the advent of endocarditis, in every case; and it cannot be said that the simple uncomplicated disease in any respect affects either the pyrexia or any other element of the same. Local symptoms are almost equally rare, unless the endocarditis leads to serious lesion of the cardiac valves. As long as these remain sound, and the disease is acute and does not involve deeper structures, pain in the heart, præcordial distress, syncope, shortness of breath, and other symptoms of heart-disease cannot be said to occur at all frequently in endocarditis. The cardiac contractions are necessarily increased in frequency; and palpitation and dyspnoea may occur on movement. It is otherwise when the inflammation has lasted so long as to render the valves incompetent, or to obstruct the orifices, or when the myocardium is attacked, and dilatation ensues. The symptoms just enumerated then make their appearance, as well as those of secondary involvement of the lungs, of the circulation, and of the system generally.

Ulcerative endocarditis, unlike the ordinary form of the disease, is manifested by severe and striking symptoms, although amongst these the phenomena of cardiac inflammation are comparatively subordinate to those of general infection. It is on this account that ulcerative endocarditis has only recently been definitely recognised as a distinct form of disease, the condition of the endocardium *post mortem* having apparently been disregarded in the presence of serious lesions of the other viscera, of the blood-vessels, and of the blood itself. Commencing with a sudden rigor, in the course of acute rheumatism, during the puerperal state in women, or in a case of chronic

valvular disease, ulcerative endocarditis either resembles a simple continued or typhoid fever from first to last, or assumes a markedly pyæmic character. In the former case, gastro-enteric symptoms and splenic enlargement may be strongly marked; whilst in the second case, vomiting, and diarrhoea, jaundice, albuminuria, and various eruptions, with pyrexia of a pyæmic or remittent type, are prominent phenomena. In both forms the case steadily progresses towards a fatal termination. A loud systolic murmur is generally present from the first, and may point to the heart as the primary seat of disease; but in ulcerative endocarditis, as in simple endocarditis, special local symptoms are rare.

Physical Signs.—The physical signs of acute endocarditis are—increased extent and frequency, with variable strength, of the visible and palpable impulse; moderate increase in the area of præcordial dulness; and various alterations in the cardiac sounds. At the beginning of endocarditis, the first sound at the left apex is frequently heard prolonged and hollow, or muffled, and, as the process advances, this alteration of character may gradually pass into a murmur, which is at first indistinct, but afterwards well-formed. If the aortic valves are affected, the second sound may similarly lose its characters, become dull, and finally be converted into, or be complicated with, a murmur. The most frequent murmur in acute endocarditis is mitral systolic, aortic murmurs are decidedly less common, and mitral præ-systolic murmur is very rare. Various inorganic murmurs may appear, and either disappear or continue during the course of the disease.

Complications.—Endocarditis is itself always a complication of the diseases previously mentioned. Myocarditis and pericarditis may be correctly regarded as complications of endocarditis, when the inflammation begins in the lining membrane of the heart. According to some authorities, clots may form in the heart in endocarditis, and give rise to very urgent symptoms (see *Heart, Thrombosis of*). Embolism may arise from detachment of fragments of coagula or vegetations, and this condition, and the development of pyæmic symptoms are essential elements in the course of the ulcerative form of the disease. Congestion or inflammation of the lungs frequently occurs in association with endocarditis, and so may albuminuria.

COURSE, TERMINATIONS, AND SEQUELÆ.—The course of simple endocarditis is very uncertain, and varies with the course of the original disease with which it is associated, as well as with the complications. If acute rheumatism be checked in a few days, inflammation of the endocardium may be expected to be also arrested. In a considerable number of cases, however, endocarditis passes on to chronic valvular disease. For example, the late Dr. Wilson found that seventeen out of seventy cases of endocarditis with mitral systolic murmur ended in established valvular disease, and less than a half of the cases with diastolic basic murmur.

Simple endocarditis very rarely proves fatal, but the ulcerative form is believed to be uniformly so in the course of a few days, or it may be weeks. On the other hand, simple endocar-

ditis, being by far the most common cause of valvular disease of the heart, leads indirectly to much suffering, and, as a rule, ultimately to death.

DIAGNOSIS.—The diagnosis of endocarditis depends upon the discovery of the development of an endocardial bruit of organic origin during the course of one of the diseases already named. From functional murmurs the bruits of valvular inflammation may be diagnosed under different circumstances—first, by their locality, which is most frequently the mitral area; secondly, by their time, diastolic or præ-systolic murmurs being always organic; and, thirdly, by their association with pericardial friction. The special characters of inorganic murmurs are described elsewhere. Chronic valvular disease may be diagnosed from acute endocarditis by the presence of cardiac enlargement and other well-known signs; of marked cardiac symptoms—especially pain and dyspnoea, and of visceral complications. Much more difficult of diagnosis is acute endocarditis occurring in the course of chronic valvular disease. Change of the character of the murmur, if this have been observed previously, may lead to the suspicion of fresh inflammation, but cannot establish the diagnosis of its existence, which may not be discoverable. The diagnosis of the precise seat of endocarditis on the various valves is discussed in the article *HEART, Valves and Orifices of, Diseases of*.

It is often impossible to diagnose ulcerative endocarditis from typhoid fever or pyæmia respectively, according to the form that it assumes; unless the ætiology of the case, the precise character of the pyrexia, and the occurrence of metastases be very carefully regarded, along with the development of a murmur at one or more of the cardiac orifices, and possibly of pericarditis.

PROGNOSIS.—The immediate prognosis of acute endocarditis is generally favourable, and may be safely estimated by the absence of local symptoms. The remote prognosis, on the other hand, as regards both life and health, is exceedingly bad, inasmuch as endocarditis so frequently ends in chronic valvular disease. The probability of this result of acute inflammation of the valves is frequently difficult or impossible to estimate. A feeble, soft, and smooth murmur, or a feeble and gray murmur, is much more likely to disappear than a loud extensive well-defined bruit. The probability of the disappearance of diastolic basic murmurs may be best estimated by the absence of the effects produced by aortic incompetence upon the heart and vessels.

TREATMENT.—The treatment of acute endocarditis has to be discussed under three heads, namely, first, preventive, secondly, immediate; and thirdly, subsequent treatment.

a. Preventive treatment.—When a patient is suffering from any disease which may become complicated with endocarditis, and especially if he be suffering from acute rheumatism, every means must be adopted to prevent, as far as possible, the occurrence of this complication. Thus, in acute rheumatism it is all-important to check at once the intensity of the disease by recourse to salicylic acid or its salts, and other means, for experience shows that endocarditis, when it does occur in acute rheumatism, generally

makes its appearance within the first week. Again, the duration of the primary disease must be curtailed if possible, inasmuch as endocarditis, although it generally appears early, may possibly occur at any period of the disease. Thus the medicinal preventive treatment of endocarditis in these cases resolves itself into the medicinal treatment of acute rheumatism. Another point of equal importance in the prevention of endocarditis is diminution of the cardiac activity. We have seen that the pressure within the heart is an important factor in the causation of endocarditis, and this pressure must be reduced by diminishing the work to be done by the heart, without lowering the cardiac power. Rest must therefore be enforced in the recumbent posture — an end which is usually already secured by the presence of acute rheumatism of the joints. The personal comfort of the patient must be zealously attended to, and pain relieved, so that restlessness and irritability may be avoided, and for this purpose carefully selected anodynes may be necessary. Stimulants must be cautiously ordered, the bowels should be regularly and fully moved, and the various secretions are to be kept as active as possible.

b. Treatment during an attack — When endocarditis has actually made its appearance, the various means just insisted upon must be enforced as rigorously as before, so as to diminish the intensity of the inflammation, and to limit the extent of surface involved. Rest is still of the first importance. The medicinal treatment of the original disease — especially of acute rheumatism — must be persevered in. Local applications to the præcordium, such as cataplasms, or, in cases of sthenic inflammation, leeching, are often of great service. The administration of stimulants will require the greatest care, excitement of the heart, on the one hand, being avoided, and, on the other hand, digitalis, ammonia, or alcohol being employed, if symptoms of cardiac distress supervene. Equal caution is demanded in the use of anodynes which may be indicated to relieve distress connected with the joints, and local applications, such as cotton-wool, poultices, acornite, and belladonna, should be employed in preference to opium, chloral, and other cardiac depressants.

In *generative* endocarditis, quinine in large doses, and salicylic acid are the remedies which appear to promise most success, and all the ordinary measures for support in fever must be persevered with.

c. Treatment after an attack. — When the primary disease, such as rheumatism, has subsided, and the restoration of the various functions indicates that convalescence has commenced, the physician must not forget the state of the endocardium that has recently been inflamed, which is probably still in a condition of great physical weakness, and the seat of new cell growth. Instead of urging the patient to sit up and walk about under these circumstances, as must have been frequently done under the 'rival methods' of treating acute rheumatism, we should recommend a very gradual return to exercise, and the most jealous avoidance of actual exertion. There can be no question that, at this stage, rest for several weeks is of more importance than medicinal

treatment. At the same time various tonic and other remedies should be employed.

II. Myocarditis. — **SYNOM.**: Carditis; Fr. *Myocardite*, Ger. *Myocarditis*.

DEFINITION. — Inflammation of the walls of the heart.

This disease may be either acute or chronic; but the latter form, which is attended with the formation of fibroid tissue in the myocardium, is described under the head of **HEART, Fibroid Disease** of **Pyæmic inflammation** of the substance of the heart also constitutes such a special form of disease that it is treated separately (see **HEART, Pyæmic Abscess** of). Acute myocarditis alone, therefore, has to be considered in the present article.

ÆTIOLOGY. — A certain amount of myocarditis is sometimes associated with acute endocarditis and pericarditis, and depends upon the same causes; the most frequent being acute rheumatism. In a small proportion of cases, rheumatic myocarditis appears to occur independently of inflammation of the lining or of the covering membrane. In the great majority of recorded cases of localised myocarditis ending in abscess, the cause of the disease was altogether obscure. It has been observed most frequently in males, and before the twenty-fifth year of life. Exposure to cold, severe exertion, and local injury are mentioned amongst exciting causes, but with questionable correctness.

ANATOMICAL CHARACTERIS. — Acute inflammation of the myocardium generally involves the connective tissue as well as the muscular fibres; but in a few instances the latter alone have been found affected, constituting so-called *parenchymatous myocarditis*.

The ordinary form of the disease is characterised by the appearance of leucocytes between the muscular fibres of the heart. In one class of cases the inflammation is moderate in intensity but diffused in extent, affecting one or more layers of muscle underlying the endocardium or pericardium, which are also inflamed; in another class of cases, the inflammation is more active, and proceeds to the formation of abscess, whilst it is, as a rule, comparatively localised.

In the first or diffused form, the myocardium, as it is seen through its inflamed covering, appears of a mottled opaque buffy colour, and is somewhat swollen and softened. The microscopical characters consist chiefly in the appearance of leucocytes and inflammatory effusion in the intermuscular connective tissue, swelling, opacity, nuclear proliferation, and rupture of the muscular fibres, followed by fatty degeneration and atrophy of the same, and the ordinary inflammatory changes of the vessels of the part. Beyond this stage, unless the case prove fatal the diffused form of myocarditis passes into a chronic condition; and it ends either in fibroid disease with a moderate amount of atrophy, by development of the inflammatory products and atrophy of the affected fibres, in fatty degeneration, in calcification; or in cardiac aneurism.

Suppuration of the heart, on the other hand generally takes the form of swollen yellowish-white patches or abscesses, surrounded by dirty-red or ecchymosed tissue, boggy or pulpy to the

finger, and containing on section a small quantity of variously-coloured puriform matter, consisting of pus and muscular debris. In the same cases a great part of the walls of the heart may be in a condition of parenchymatous degeneration; and in some recorded instances the whole of the cardiac tissue is described as infiltrated with pus. Abscesses resulting from acute localised myocarditis are generally very small, varying from the size of a pea to that of a nut. They may either burst externally into the pericardial sac, or internally into one of the cavities or through one of the valves, leading to pyæmia, and to the formation of an acute cardiac aneurism; or the pus may make its way both externally and internally, and lead to fatal hæmorrhage into the pericardium. In other cases the pus undergoes the usual changes, and becomes inspissated or cheesy, or calcification takes place.

In both forms of interstitial myocarditis the left ventricle is most frequently the seat of inflammation.

SYMPTOMS.—The principal symptoms of acute rheumatic myocarditis are restlessness and urgent dyspnoea, severe pain and distress referred to the præcordium, and palpitation, which gradually passes into irregularity and greatly increased frequency, and finally into complete cardiac failure. The pulse corresponds. The countenance is anxious and pale, or cyanosed. The mind is fearful and distressed at first, and delirium frequently supervenes before death, especially in young subjects. Vomiting is not uncommon.

The physical signs are generally associated with those of endo- and pericarditis, but when uncomplicated may be described as—violent cardiac impulse at first, which rapidly loses in strength and regularity, while it increases in frequency, a somewhat increased area of cardiac dullness; and short sharp sounds, afterwards becoming duller and more feeble.

When these symptoms and signs make their appearance, they generally run their course rapidly, and end in death. In a small number of cases they as rapidly disappear.

The symptoms of localised suppurative myocarditis leading to abscess are not unlike those just recorded. There are the same distressing symptoms locally, with restlessness and anxiety, passing on to delirium, and ending in collapse. Rigors have been observed in some cases, and a peculiar pustular eruption on the skin in other cases. The physical signs also are not special, excepting that a murmur may be suddenly developed by rupture or perforation of part of the wall or of a valve.

The majority of cases of abscess of the heart prove fatal by asphyxia; but the other terminations of abscess mentioned above will be attended by their respective symptoms, and the possibility of sudden death is especially to be noted.

Diffuse parenchymatous myocarditis is clinically known only as a cause of sudden death.

COMPLICATIONS.—The complications of acute myocarditis have already been sufficiently indicated, such as, first, etiological, pericarditis, endocarditis, acute rheumatism, and other causes of these forms of inflammation; and, secondly, pathologically, rupture of the cardiac walls or

valves, acute cardiac aneurism, hæmopericardium, embolism, and septicæmia.

COURSE AND TERMINATIONS.—The course of acute interstitial myocarditis, as already stated, is generally rapid, extending from a few hours to eight days in different cases. Death occurs, in the great majority of cases from the effects of cardiac failure, if the inflammation be extensive or proceed to suppuration. The formation of acute aneurism by internal rupture, the production of pericarditis by external rupture, and other complications will variously modify the progress and termination of cardiac abscess. Simultaneous rupture both externally and internally causes sudden death.

DIAGNOSIS.—The diagnosis of acute myocarditis is extremely difficult. Occurring in connection with acute rheumatism, it has to be distinguished from endo- and pericarditis. The absence of murmur and of the characteristic signs of pericarditis, along with symptoms of cardiac failure and severe local phenomena, such as pain, distress, dyspnoea, and finally collapse, should generally serve to establish the diagnosis of inflammation of the walls of the heart. It cannot be said that cardiac abscess has ever yet been diagnosed, but the careful consideration of all the points in the case, and the sudden development of a murmur indicative of rupture of portion of the wall, or of a valve, may hereafter ensure greater success. In the event of the development of the last-named sign, and of septicæmia or embolism, cardiac suppuration would have to be carefully diagnosed from ulcerative endocarditis. In children, acute myocarditis has to be distinguished from acute meningeal inflammation, an object which may be effected by the careful observation of the signs and symptoms connected with the heart.

PROGNOSIS.—The prognosis of myocarditis, when it is either so extensive or so intense as to give rise to unequivocal symptoms, is extremely unfavourable.

TREATMENT.—The two principal indications of treatment in acute inflammation of the substance of the heart are to support and strengthen that organ, and to relieve the pain and distress. Local anodynes, especially in the form of the preparations of belladonna and poultices; and stimulating 'counter-irritants,' such as mustard cataplasms, will conduce to fulfil the second indication. Such relief is the first essential, if rest is to be secured. The patient must be spared the very smallest exertion. Food must be given in small quantities, and be easily digestible and highly nutritious, the bowels must be kept open, and the flow of urine should be as free as possible. Alcoholic stimulants will be urgently called for, and palpitation may be regarded as an indication of the necessity for these, as much as weakness of the impulse. Digitalis, ammonia, and other cardiac stimulants should be given cautiously, at the same time, so as to strengthen the cardiac action, whilst diuresis is encouraged.

J. MITCHELL BRUCE.

HEART, Malformations of.—**SYNON.**: Fr. *Affectons Congénitales du Cœur*; Ger. *Misbildungen des Herzens*.

CLASSIFICATION AND DESCRIPTION.—The car-

diac anomalies of development may be classed as follows:—

I. Those dependent on arrest of the process of development at an early period of fetal life, so that the organ retains its most rudimentary form, the auricular and ventricular cavities being still single or presenting only slight indications of division, and the primitive arterial trunk being retained, or the aorta and pulmonary artery being very imperfectly evolved.

II. Those in which the defective conformation occurs at a more advanced period, when the auricular and ventricular partitions are already partly formed, and the aorta and pulmonary artery more or less completely developed. Such are the cases in which, with imperfect separation of the ventricles and auricles, the arterial or auriculo-ventricular passages are constricted or obliterated, and the origins of the aorta and pulmonary artery are misplaced.

III. Cases in which the development of the organ has progressed regularly till the *later periods of fetal life*, so that the auricular and ventricular septa are complete, and the primary vessels have their natural connections, but in which there are defects which prevent the heart undergoing the changes which should ensue after birth—such are the premature closure of the foramen ovale, the non-development of the ductus arteriosus, or the occurrence of slighter sources of obstruction at the arterial or auriculo-ventricular passages or in the course of the aorta.

IV. Cases in which there is some irregularity in the formation of the valves, or in the connections with the vessels, or in the vessels themselves, which, though not immediate sources of obstruction, may become so during the progress of life, so as to lay the foundations of subsequent disease.

I. Cases of the first class are of very infrequent occurrence, and are the more rare according to the extent of the imperfection. The first case of simply biloculate heart was placed on record by Mr. Wilson, in the *Philosophical Transactions*, in 1788, and the specimen is preserved in Dr. Baillie's museum, in the possession of the Royal College of Physicians. The anomaly was found in the body of a child, which survived for seven days. From defect in the diaphragm, the heart lay in a sac on the upper surface of the liver, and the organ was found to consist of an undivided auricle and ventricle, and a single artery, evidently the primitive arterial trunk, which first gave off a vessel which furnished the branches to the lungs, and the vessels to the head and upper extremities. The coronary arteries arose by a common trunk from the aorta before its final division. Since the publication of this case, others have been placed on record illustrating the gradual advancement from the simplest to the more complicated forms—the ventricle becoming more completely divided, the septum of the ventricles being more fully developed, and there being two vessels given off from the ventricle, though in some cases one of these may be abortive, or if there be only a single vessel, that being shown by the origin of the coronary arteries from its commencement to be really the aorta.

II. Of the second class, the examples which

have been described are much more numerous. In cases of this kind the auricles and ventricles are fully formed, though the septa which divide them are incomplete, and there is usually more or less displacement of the origins of the primary vessels, so that the aorta more especially may come to arise partly or almost entirely from the right ventricle; or the points of origin of the vessels may be transposed, the aorta arising from the right ventricle, and the pulmonary artery from the left. Cases of the former description, in which the septum of the ventricles is incomplete, and the aorta misplaced to the right, are almost always found to coexist with some obstruction to the passage of the blood from the right ventricle, either (1) from smallness of the pulmonary artery, (2) from imperfection of the valves, (3) from constriction at the outlet of the right ventricle, or at the end of the conus arteriosus or infundibular portion of the ventricle; or (4) from constriction at the commencement of the conus or point of union between that portion of the ventricle and the sinus. A case of the second description was published by Sundfort, in 1777, and one occurred to Dr. Hunter in 1761, but was not published till 1763. The fourth form of obstruction, or that occasioned by constriction between the sinus and the infundibular portion of the right ventricle, has only recently been explained, though cases of the kind have for some years been placed on record. It is indeed probable that the existence of a very decided partition in this situation led to the idea entertained by some of the older pathologists, that the heart occasionally had three ventricular cavities. The abnormal septum is partly formed by hypertrophy of the muscular structure, and partly by the endocardium becoming thickened, and in some cases very decided obstruction is so caused. The defect is generally developed at an early period of fetal life. The septum of the ventricles is therefore incomplete, the defect being at the posterior part, so that the aorta comes to arise from the sinus of the right ventricle, while the pulmonary artery takes its origin from the infundibular portion, which seems to constitute a distinct cavity. The heart thus, as pointed out by Mr. Grainger, bears an almost exact resemblance to the condition of the organ in the turtle. In the turtle there are two aortic ventricles and one pulmonic ventricle; the right aortic and the pulmonic ventricle being the analogues of the sinus and infundibular portion of the right ventricle, and being in connection, while the left aortic ventricle is distinct.

Much more rarely there has been found an entire obliteration of the orifice or trunk of the pulmonary artery, the first case of this description of anomaly having also been published by Dr. Hunter at the same time as the former case. Much more rarely the defect in the ventricle has been found in connection with obstruction or obliteration of the right auriculo-ventricular, the left auriculo-ventricular, or the aortic aperture. Where the septum of the ventricles is incomplete, the defect generally exists at the base, at the part which has been termed the *undefended space*—the space which intervenes between the contiguous sides of the left and posterior semilunar segments, where on the left side the muscles in

naturally deficient; and in this way a connection may exist between the left ventricle and right auricle or ventricle, either immediately above or below the right auriculo-ventricular opening. More rarely the septum between the left ventricle and the conus arteriosus of the right ventricle is defective; and still more rarely an aperture exists at a lower part of the septum. The portion of the septum dividing the left ventricle from the sinus of the right is termed by Rokitanaky the posterior—that between the left ventricle and conus arteriosus, the anterior septum. With the defects now mentioned, the auricular septum may also be incomplete, or the foramen ovale may be still open, or the ductus arteriosus pervious. Indeed, when the pulmonary artery is much contracted or impervious, one or other of the former conditions necessarily exists, and the ductus arteriosus becomes the means by which the blood is conveyed to the lungs, though occasionally there are compensatory branches derived from the aorta or one of the large vessels also distributed to the lungs.

The transposition of the aorta and pulmonary artery also occurs at an early period of fetal life. The first case of the kind recorded was related by Dr. Baillie in 1797; the specimen is figured in his plates, and still exists in the museum in the possession of the Royal College of Physicians. In this anomaly the septum of the ventricles is generally defective, and the two fetal passages open, and the organ may indeed be very defective in conformation. The heart also is often misplaced in the chest. Another form of defect is that in which the descending aorta is given off from the pulmonary artery through the ductus arteriosus. This condition is apparently the result of imperfect development of the isthmus aortæ between the origin of the left subclavian artery and the point of entrance of the duct, so that an adequate supply of blood cannot be conveyed from the ascending into the descending aorta. Generally the condition coexists with defect of the septum of the ventricles, as in two cases formerly in the possession of Sir Astley Cooper, and now contained in the museum of St. Thomas's Hospital, described by Dr. Farre in 1814. In some instances of this kind the portion of aorta between the left subclavian artery and the duct is imperforate, and yet in others, as in a case related by Steidelle and referred to by Hoin in 1816, there is no connection between the two portions of the aorta, the ascending part giving off the vessels to the head and upper extremities, the descending portion being wholly derived from the pulmonary artery. This form of defect is closely allied to the cases which are occasionally seen in after-life, in which there is constriction or obliteration of the isthmus aortæ beyond the left subclavian artery, the circulation being maintained through collateral channels.

III. The third class of cases consists in the premature closure of the foramen ovale; or the non-development or disappearance, at an early period of fetal life, of the ductus arteriosus; or in diseased conditions of the valves, which prevent the heart undergoing the changes which should ensue after birth.

The first condition is of very rare occurrence.

The first case recorded was related by Vieussens

in 1718. In these cases the blood during fetal life being all transmitted through the right cavities and the pulmonary artery and duct, those portions of the heart are unduly developed, while the left side of the organ becomes atrophied. In the second class of cases the heart is defectively developed, and the right ventricle gives origin to the aorta, and often also vessels are distributed from the aorta to the lungs, while the ordinary pulmonary artery may be very small in size, or may be entirely absent. In a case of this kind, described by Dr. Ramabotham, the pulmonary artery is said not to exist, but by examination of the specimen preserved in the London Hospital Museum, the writer has ascertained that this is not correct. The artery exists as a very small vessel, but the scanty supply of blood to the lungs which it furnished was complemented by small vessels from the aorta. In cases which are not of uncommon occurrence, and may be classified with the malformations now spoken of, but which are closely allied to the next class, there exists some source of obstruction to the transmission of the blood from or into the right ventricle, which determines the imperfect closure of the foramen ovale, or the patency of the ductus arteriosus. The obstruction in these cases generally depends on disease of the pulmonary valves, or obstruction at the end or beginning of the conus arteriosus, or at the right auriculo-ventricular aperture.

IV. The fourth class of malformations consists of defects, of a slighter description, of the valves, or narrowing of the orifices, or of the isthmus aortæ.

The semilunar valves may be excessive or defective in number. The former condition probably does not materially interfere with the functions of the heart—the latter often does so, and especially when, as is very frequently the case, the valves become the seat of disease in after-life. If there be only two valves, one of them imperfectly representing two distinct segments, there is great liability to incompetence. If there be only one valve, representing three imperfect segments, obstruction is almost necessarily occasioned.

It is probable that the cases in which the tricuspid valve is found represented by a kind of membranous diaphragm, stretched across the orifice and perforated in the centre, and some of the so-called cases of button-hole mitral, are also of congenital origin.

It is not considered necessary in this article to refer to many examples of these different forms of malformation, or to allude to other of the less important deviations from the natural conformation of the heart. The subject will be found more fully treated of in the works of Dr. Farre¹ and Gintrac² and Freidberg,³ in the papers of Dr. Chevers,⁴ and in the writer's own work.⁵ The more recently published cases also are ab-

structed in the treatise of Taruffi,¹ and numerous examples of different forms of malformation are given by Rokitanaky.²

MODE OF FORMATION.—It is probable that all the different forms of irregularity in the development of the heart are due to arrest of development, occurring at different periods of evolution, so that the heart retains the forms proper to it at such stages. The cause to which this arrest is to be ascribed can rarely, however, be traced in cases where the defect is great, such as those of biloculate heart, or where the vessels are transposed with or without very marked imperfection in the organ itself. These defects must be ascribed to the imperfect evolution of the double set of cavities, and of the pulmonary artery and aorta from the primitive trunk and branchial arches. In the less marked defects, however, the irregularity can often be traced to a source of obstruction to the transmission of the blood through one or other of the apertures or vessels. Such obstruction is much the most common in connection with the right ventricle and pulmonary artery. In cases of this kind the septum of the ventricles is deficient, so that the aorta arises wholly or in part from the right ventricle. Dr. Hunter, in the paper before referred to, when describing a case of obstruction of the pulmonic orifice with defect in the septum of the ventricles, suggested that the imperfection in the septum was probably caused by the pulmonic obstruction. Meckel, however, adopted the view that the primary defect was in the septum of the ventricles, and that the pulmonary artery became more or less abortive from being thrown out of the course of the circulation by the ready outlet afforded for the blood from the right ventricle into the aorta. The former view seems, however, to afford the more satisfactory explanation, and is in accordance with the almost constant occurrence of disease of the valves in these cases. According to the view of Meckel, the pulmonary artery should simply be small, as when the ductus arteriosus is absent, like the case of Dr. Ramsbotham before referred to, but such a condition is very rarely found. The excess in the number of the semilunar valves might seem to afford an example of redundant development, but this condition also probably depends on arrest of development, though, as we do not clearly understand the mode in which these valves are developed, it is impossible to express a very decided opinion as to the cause of the apparent excess.

SYMPTOMS AND DIAGNOSIS.—There cannot generally be much difficulty in recognising a case of malformation of the heart during life. Not only in cases of a very marked kind is there generally a complete history of the condition of the subject during its short life, but the symptoms are also very characteristic. The child is very markedly cyanotic; the cheeks, lips, hands, and feet are excessively livid, the fingers and toes are clubbed; the nails are incurved; and the patient is liable on any excitement, or on exposure to cold, to attacks of dyspnoea, often followed by convulsions. There are also often present difficulty of breathing, cough, and

expectoration of blood; with palpitation, and often pulsation of the vessels of the neck. If also there be any obstruction at or near the pulmonary orifice, there will be a harsh systolic murmur heard in the course of the pulmonary artery; and if there be a defect in the septum of the ventricles, the murmur will be heard probably also in the course of the aorta. Often there are unhealthy ulcerations about the fingers, toes, and anus or vulva. If the case do not attract notice till late in life, there will probably be less marked signs of obstruction to the circulation, and possibly they may be entirely absent, and there may be no history of the patient's previous condition. In cases of this kind the probability will be that if there is a murmur at the pulmonary artery there is some defect at or near the orifice of that vessel, with or without an aperture in the septum of the ventricles or an open state of the ductus arteriosus. The former condition is so rare as the result of disease in after-life, that if the signs point to pulmonic valvular disease, its congenital origin may safely be surmised. The open foramen ovale and ductus arteriosus could probably not be diagnosed with any certainty, though cases have occurred in which peculiar murmurs noticed during life were supposed to be so produced. It might be supposed that when so small a proportion of the blood is subjected to the influence of the air, as in some of these cases, the temperature of the patient would not reach the natural standard, but the most careful observation of the temperature of children labouring under congenital cardiac cyanosis has generally failed to detect any marked difference between them and other children of about the same age.

Cyanosis.—There are few subjects which have excited more discussion than the causes of Cyanosis or *Morbus Carulus*. Morgagni, in 1761, when describing the case of a girl who had obstruction at the orifice of the pulmonary artery with an unclosed foramen ovale, expressed the opinion that the general congestion was probably the cause of the remarkable lividity which had been noticed during life, and Dr. Hunter, in 1783, in describing a case of pulmonic obstruction with imperfection in the septum of the ventricles, ascribed the lividity to the intermixture of the venous and arterial currents of blood. These views have since received support from various writers. The view of Morgagni has been maintained by Louis, and that of Hunter by Guitrae. It has been very fully shown that there is no just and constant relation between the intensity of the cyanosis and the amount of intermixture, and indeed that very marked cyanosis may exist without any intermixture; while on the other hand in all cases of marked cyanosis there are present anæses capable of producing great venous congestion. The writer is, therefore, of opinion that the evidence is very greatly in favour of the correctness of the views of Morgagni and Louis, that the cyanosis results from stasis of the blood, though probably other causes conduce to the intensity and peculiarity of discoloration. Thus, probably, the defect must be congenital, or, at least, of very long duration, so that the smaller vessels may become greatly dilated; the integuments must be thin, so as to allow the colour of

¹ *Scille Anatômie comparée, etc. del cuore*. Bologna, 1876.

² *Die Defecte der Hohlwand des Herzens*. Wien, 1876.

the blood more readily to be seen, and lastly—probably also from the very small portion of the blood which can be subjected to the influence of the air—the whole mass is of an unusually dark colour, and so the intensity of the lividity is increased.

DURATION AND TERMINATIONS.—The duration of life in the subjects of the different forms of malformation varies greatly, according to the degree of the defect in the heart. In cases in which the organ presents a very rudimentary condition, life can only be prolonged for a few hours or days; while in the slighter forms of defect the patient may survive to puberty or to manhood or womanhood, or even to more advanced age. Thus, in cases of contraction of the pulmonary artery, without other defect in the organ, cases are on record in which patients lived to 44 and 63, when, with the pulmonic disease, the foramen ovale was unclosed, the subjects have reached 40 and 57. Where the septum of the ventricles was deficient, nine patients are stated to have lived to between 20 and 30. Where the ductus arteriosus was still open, patients lived to 13½ and 19 years, but of course these ages are the extremes, and by far the largest proportion of the subjects die much younger. When the pulmonic orifice or artery is imperious, but few patients survive for more than two years, but cases are on record in which 9 and 12 years of age were attained, the age being greater according to the facility afforded for the transmission of the blood from the right side of the heart, as when the septum of the ventricles was imperfect, than when the ventricles were completely separated.

Transposition of the aorta and pulmonary artery is a defect incompatible in any of its forms with the prolongation of life for any lengthened period. Four cases are, however, on record in which the patient survived to between 2 and 3 years of age—the imperfection of the septum of the ventricles tending in these cases also to the prolongation of life.

The most common causes of death in cases of malformation of the heart are affections of the brain and lungs, hæmoptysis, &c.; and, if the patient survive for a sufficient period, tuberculous affections. Notwithstanding the very great obstruction to the circulation, dropical symptoms do not generally arise to any marked degree.

TREATMENT.—It is scarcely necessary to speak of the treatment of these cases. It must consist in protection against cold, in the maintenance of bodily and mental quiet, and in the use of a nutritious and easily digestible diet.

T. B. PRACOCK.

HEART, Morbid Growths in.—The various forms of morbid growth that have been met with in the heart may be thus enumerated in the order of their frequency:—1. Malignant disease; 2. Lymphomatous or lymph-adenomatous growths; 3. Non-malignant tumours, and 4. Cysts. Fibroid growths, syphilitic gummata, and tubercle, as well as hydatids affecting the heart, are discussed separately under their respective heads. Calcareous, cartilaginous, and caseous changes of the myocardium are noticed in the article **HEART, Degenerations of.**

I. Malignant Disease of the Heart.—Cancer, although the most common of the new formations found in the heart, is still very rare in this situation, and is a subject chiefly of pathological interest.

ÆTIOLOGY.—Malignant disease of the heart is, with very few exceptions, always secondary; and the primary growth may have its seat in any part whatever of the body. Occasionally the heart becomes involved by continuity, the lungs and mediastinum being the seat of the primary disease. Cases have occurred at all periods of life, from infancy to old age; but at least one-half of the subjects have been in the middle period of life. The disease has been most frequently found in males.

ANATOMICAL CHARACTERS.—Carcinoma, epithelioma, and sarcoma, including colloid cancer and melanosis, have all been found in the heart in different instances. Any part of the organ may be affected, and the right side appears to be more frequently invaded than the left, but the disease is generally multiple. The morbid growth generally presents itself at or upon either of the surfaces of the heart, rather than in the substance of the myocardium. In those situations there appear one or more masses of malignant disease, which are generally easily distinguished from the cardiac tissue around; and which possess the ordinary characters of such formations, according to their respective forms, encéphaloid being the most common, and epithelioma by far the most rare. Any difficulty in the recognition of the disease is removed by section and microscopical examination. The extent of cardiac wall involved by the growth is sometimes great. When the masses of malignant disease project externally, they are frequently associated with pericarditis, either local or general. Prominent nodules in the interior of the heart may cause local endocarditis, and in other instances the valves and their appendages may be so involved that incompetency results. In very rare cases malignant disease of the heart proceeds to ulceration.

SYMPTOMS.—Of thirty-six cases of malignant disease of the heart, the histories of which were collected by Dr. Quain, in thirty either there were no symptoms present, or they were not recorded. In one of the remaining six cases, the subject of the disease, a man of thirty-seven, in whose heart a single large mass of encéphaloid cancer was found *post mortem*, had been subject to attacks of excruciating pain in the præcordial region, to dyspnoea, palpitation, and vomiting; and death occurred suddenly. Pain in the chest and oppression, not referable to other causes, are recorded in two other cases; and in the fourth there were anginal seizures. In cases of cancer of the heart spreading from the mediastinum or lungs, dyspnoea, cough, and pain are necessarily frequent symptoms.

With respect to the physical signs of malignant disease of the heart, tenderness on percussion over the præcordium (in association with local pain), pericardial friction, and endocardial murmurs due to involvement of the valvular apparatus in the new growth, appear to be the only phenomena that have been specially observed.

The disease naturally ends in death; and in

more than one instance this termination was sudden, and perhaps directly due to the affection of the heart.

DIAGNOSIS.—This condition has probably never been diagnosed during life. The appearance of true cardiac pain, or of any of the physical signs just mentioned, in the course of a case of cancer, would, however, be strong evidence that the heart was secondarily involved.

TREATMENT.—The treatment of malignant disease of the heart is necessarily limited to the relief of any symptoms that may be present, and does not differ from the treatment of cardiac distress from other causes.

2. Lymphoma of the Heart.—Lymphomatous or lymphadenomatous growths have been met with in the heart in several cases in which the disease was general, but this affection of the organ cannot be said to have any clinical importance.

3. Non-Malignant Tumours of the Heart. These growths are also of purely pathological interest, and are amongst the very rarest of morbid appearances in connection with the heart. *Myxomata* have been recorded as instances of this class of diseases. *Lipomata* lying under the endocardium are referred to in the article HEART, Fatty Growth on.

4. Cysts of the Heart.—The occurrence of true cysts in the myocardium (hydatids, abscesses, hematomata, and softening gummatas being excluded) is doubtful.

J. MITCHELL BRUCE.

HEART, Palpitation of.—SYNOV.: Fr. *Palpitation du Cœur*; Ger. *Herzklopfen*.

DEFINITION.—Abnormal movement of the heart, whereby the force of the systolic contractions is increased to such a degree as to give rise to a sensation of discomfort or distress on the part of the patient.

ÆTIOLOGY.—The immediate or proximate cause of palpitation is an over-stimulation of the excitability of the muscular structure of the heart, induced by functional errors of the cardiac ganglia and of the vagus, or of those nerves which, proceeding from the ganglia of the great sympathetic, supply the heart. It is therefore a true neurosis. The disordered action of these nerves may be induced either directly or by reflex action, but in either case the phenomena as regards the heart are the same, namely the morbid activity of a normal function, which must be here considered as independent of any accompanying organic lesion.

The predisposing and exciting causes of palpitation of the heart are various. The chief predisposing causes are to be found in the nervous and excitable temperaments, general debility; inanition, exhaustion, whether bodily or mental; early age; hysteria, venereal excesses, and in deterioration of the blood, as occurs in gout, scurvy, chlorosis, or spæmia. Amongst the exciting causes may be classed violent exercise; mental shock, emotion, and all forms of sudden excitement of the nervous system; dissipation; injurious articles of diet; and dyspepsia.

SYMPTOMS.—Palpitation may be found in the form of (1) a single action; or (2) a series of actions, which may become prolonged, and of such

a character as to be esteemed chronic. The single abnormal beat not unfrequently occurs during a first sleep, and the patient is awakened by a consciousness of it. Sleep may then return, and the attack subside without other inconvenience; or it may be associated with a feeling of weight, fullness, anxiety, sinking, or even pain of the precordia. More frequently, however, the attacks are prolonged and paroxysmal, recurring with an accelerated and uncertain frequency, and varying rapidly. In the patient the act of palpitation causes various and widely different sensations. There may be a mere occasional flutter, or a slightly increased action continuing for a time; or there may be increased action attended with great rapidity, and such violence that the heart appears forcibly to strike the chest-wall, diffusing its influence over the whole sternal region, and even at times agitating the whole body (a phenomenon probably due to an associated general nervous agitation), or the heart, again, may seem to the sufferer to rise, as it were, into the throat. With these several forms there may be the accompanying symptoms of choking—the *globus hystericus*, vertigo, tinnitus aurium; impaired vision, with a feeling of distension of the eyeballs; a copious secretion of pale limpid urine, a clammy coldness of the extremities; fear of death, partial unconsciousness, or actual syncope. Paroxysms such as these may be preceded by a somewhat prolonged state of cerebral disturbance, as evidenced by heat of brow and vertex, headache, and an inaptitude to think or regulate the thoughts, and as there is generally a self-consciousness of the abnormal action of the heart, the anxiety on this account serves to impress the mind with so much fear and inquietude, as to tend to increase and prolong the disorder that has induced them.

PHYSICAL SIGNS.—The physical examination of the heart shows the apex-beat to be normal in position, but diffused and much exaggerated in force. The area of dullness, as a rule, is not enlarged upwards, but it may be temporarily enlarged, under certain circumstances, towards the right side. The sounds, always exaggerated, at times become very much so, and usually with a sharp metallic ring. Occasionally a kind of remitting humming sound is superadded, and may be heard even by the patient, but this is never constant. Sometimes the sounds are heard over a great extent of surface, but this extent is no measure of their intensity, for they may not be loud, but abnormally clear and distinct only. Occasionally there is a pericardial rubbing accompanying the mitral apex-shock, simulating the friction-sound of pericarditis, but there is never true friction sound. The basic second sound, more frequently than the first, presents the metallic ring. Sometimes it becomes lower-pitched and less clicking than in an ordinary paroxysm of palpitation, and may even, as also the first sound, so lose sharpness and abruptness as to assume somewhat of the character of a soft murmur. The aorta, carotids, and large arteries also throb, and have an excited impulse. The smaller arteries are not sensibly affected. The pulse at the wrist is often no indicator of the amount of action exhibited by the heart. Sometimes it has the character of being sharp and

jerk, without force; or, should the right side of the heart become loaded with blood, it may be small and soft, and weak. On the subsidence of a paroxysm, the ventricular impulse may drop to its natural force and frequency, and the sounds be unaccompanied by any exaggerations. Nevertheless, though the attack may have subsided, there may be some slight irritability of the heart's action perceptible for some short time afterwards.

DIAGNOSIS.—Though the diagnosis of palpitation of the heart in some cases may present difficulty, yet, in the absence of evidence of structural lesion, an increased impulse presenting the above distinctive characters may be assumed to be functional in its origin, and not dependent on any organic disease of the heart itself. We have, in fact, to do with an exaggeration, sometimes highly marked, of the natural nervous susceptibilities of the heart; and this nervous increase of impulse, even when only slight, is usually more appreciated by the patient, more painful, and more a source of anxiety than is that attending organic disease, especially in its earliest stages.

TREATMENT.—The treatment of palpitation should in every case be directed to remedy or to remove the exciting cause of the attacks, and to render the nervous system less susceptible. In the simpler forms that which is prophylactic is all that is necessary. In more marked attacks general care, with quiet, may be sufficient; or the administration of an alkali with warm restraints. In the protracted and severer forms of attack, besides ether and ammonia, digitalis, scintilla, colchicum, chloral hydrate, and the bromides may be occasionally resorted to.

T. SHAPPEE.

HEART, Pyæmic Abscess of.—DEFINITION.—Abscess of the heart occurring in pyæmia.

ÆTIOLOGY.—Abscess of the heart has been most frequently observed in cases of pyæmia following acute necrosis of bone or diffuse periostitis, and less frequently after phlebitis, chronic or acute arthritis, urethral stricture, chronic abscess, and cancerous ulceration. In eleven out of fourteen cases, the histories of which were collected by Dr. Quin, the age of the patients was seventeen years or under, and twelve out of the same fourteen cases were males. In other words, pyæmic abscess of the heart has been most frequently found in cases following injury to a bone or to a joint in boys. In older subjects it has been associated with pyæmia secondary to one or other of the diseases just mentioned. In a few cases no primary disease was discovered.

ANATOMICAL CHARACTERS.—Pyæmic disease of the walls of the heart has been most frequently observed in the left ventricle, towards the base and in the papillary muscles. In the great majority of cases, pericarditis co-exists, and very frequently endocardial inflammation also. The pyæmic foci are generally multiple; and appear at first as small, slightly elevated, yellowish or buff-coloured, softened patches, projecting either on the external or on the internal surface of the heart, and covered with in-

flammatory deposit. On section, these patches either present an appearance of diffused yellowish softening, or contain one or more collections of dark dirty puriform matter, with ragged, ill-defined boundaries, as if formed by destruction of the discoloured tissue around, and varying in size from that of a pea to that of a pin's head.

Microscopically examined, the yellowish patches prove to be portions of the myocardium which are infiltrated with pus and granular matter; the muscular tissue itself being in a condition of granular osseous degeneration. The puriform material represents an advanced stage of the same change, consisting of granular matter and other muscular debris, blood, and frequently pus-corpuscles. The several stages of the pyæmic process have been found side by side in some cases; and emboli have been discovered in the branches of the coronary arteries, where they may have served as the foci of the abscesses. The walls of the heart are sometimes in a condition of softening throughout. Pyæmic abscess of the heart occasionally bursts; and the contents either make their way into the left ventricle—producing cardiac aneurism, and perhaps giving rise to further embolism and pyæmic disease—or into the pericardial sac.

SYMPTOMS.—Whatever the symptoms of pyæmic abscess of the heart may be, they have in recorded cases been completely obscured by the general symptoms of pyæmia, and by the local symptoms and signs of pericarditis. Thus, the patients are described as presenting a febrile, typhoid, or pyæmic appearance, an anxious look, dyspnoea, and præcordial pains; pericardial friction has been generally discovered over the heart. Delirium probably occurs more frequently than in ordinary cases of pyæmia, but may be referable to the accompanying pericarditis. The physical signs found in these cases are chiefly those of acute pericarditis. Sometimes an endocardial bellows-murmur may be heard, due either to valvular lesion, or to the formation of an acute aneurism of the cardiac wall.

COURSE AND TERMINATIONS.—The cases of pyæmia in which the heart has been found *post mortem* to be involved, have generally proved rapidly fatal, the patients dying from exhaustion. Rupture of the abscess in either direction may tend to accelerate the fatal termination; but complete rupture of the wall in both directions, with sudden death from hemo-pericardium, as in non-pyæmic abscess of the heart, does not appear to be on record.

DIAGNOSIS.—In every case of pyæmia the physical condition of the heart should be regularly investigated, and there should no longer be any risk of acute inflammation of the heart or pericarditis being mistaken for meningitis or simple delirium. Pyæmia with multiple arthritis and involvement of the heart is more difficult of diagnosis from ordinary acute rheumatism with cardiac inflammation, and mistakes in such cases have not unfrequently occurred. The history of the case, including the evidence of a definite injury, however slight, is of the greatest value; but a careful consideration of all the facts of the case alone can prevent mistakes. The only difficulty that remains in the diagnosis of pyæmic abscess of the heart is the determination of its

existence in the presence of pericarditis, which is rarely absent. For this purpose the facts of the etiology of the case are more important than the symptoms, and especially the occurrence of an injury to the pericostum of a youthful subject as the original cause of the pyæmia. As a matter of fact, the symptoms, either general or local, appear never to have suggested the diagnosis of pyæmic abscess of the heart.

DIAGNOSIS.—If a diagnosis of abscess of the heart can be made in pyæmia, the only possible prognosis that can be given is one of speedy death.

TREATMENT.—The treatment of pyæmia affecting the heart cannot be said to differ in any important respect from that of ordinary cases of the disease (*see* PYÆMIA). The accompanying pericarditis will call for local treatment.

J. MITCHELL BRUCE.

HEART, Rupture of.—The heart is liable to rupture from external injuries, and from causes acting from within. The latter are called spontaneous ruptures, and these only will be considered here. Spontaneous ruptures may affect either the walls or the valves. The latter form of lesion will be found discussed under the head of **HEART, Valves of, Diseases of**.

ÆTIOLOGY.—Rupture of the walls may be said never to occur spontaneously when the heart is healthy. The following have been enumerated by different writers as the diseased conditions of the heart's walls that *predispose* to rupture:—a thin or atrophied condition, simple softening, a 'gelatiniform' condition of the walls, apoplectic or hæmorrhagic effusion into the walls, abscess, ulceration, and fatty degeneration. The writer finds from a table of 100 cases of rupture, the histories of which he has collected from different sources, that the heart had undergone fatty degeneration in 77, in 6 the walls were described simply as being softened, in 1 there was rupture of an aneurismal dilatation; in 1 there was bursting of an abscess; in 12 the heart is said to have been healthy in texture, or not to have been examined, but in most of these latter cases mention is made of the previous existence of endocarditis, or of changes in the coronary arteries, fully justifying the impression that there was disease of the texture of the heart.

The influence of *age* in relation to rupture of the heart can be distinctly traced. For example, of the 100 cases just referred to, 63 were above the age of sixty years. Arranged in decades, the cases stand thus:—2 were between ten and twenty; 1 between twenty and thirty, 3 between thirty and forty; 6 between forty and fifty, 13 between fifty and sixty; 23 between sixty and seventy; 24 between seventy and eighty; 6 were over eighty, and in 2 the age is not stated. With respect to *sex*, of 98 out of 100 cases in which it is mentioned, 54 were males and 44 females.

The *exciting cause* of rupture of the heart is usually some mental excitement or physical effort; but the accident may occur when the subject of it is at rest, or pursuing the ordinary avocations of life.

ANATOMICAL CHARACTERS—*Seat.* In 76 cases out of the 100 to which we have already alluded,

the left ventricle was the seat of the rupture; and in 43 of these cases the lesion was in the anterior wall. The right ventricle was found ruptured 13 times, nine instances occurring in its anterior wall. The right auricle was ruptured seven times; the left auricle twice; and a rupture was found in the septum four times. These results correspond remarkably with those of other writers on the subject. Elläume (*Mon. des Hôpit.*, 1858) in 55 cases found the rupture 43 times in the left ventricle, seven times in the right ventricle, three times in the right auricle, and twice in the left auricle.

On examining a heart in which rupture has occurred, the torn part is found to present different characters in different cases. The lesion may be *complete*, causing perforation of the walls, or it may be *incomplete*. In *complete* rupture the opening is sometimes barely sufficient to admit a probe, whilst in other instances it may be two or three inches in length. The rent is sometimes longer externally, and sometimes it is longer internally. There may be but one, or there may be more than one, rupture, and in the latter case the ruptures may or may not communicate with one another. In *incomplete* rupture the injury may be confined to the internal surface, or to the external surface, or it may occur in the substance of the walls. The edges of the rent are ragged, irregular, and sometimes echymosed. The irregularity of the edges is due to the manner in which the muscular fibres are torn, whether across or split longitudinally. This description refers more correctly to rupture in a heart that is the subject of fatty degeneration. The appearances are different when the rupture is secondary to an abscess, or to ulceration, or to certain other causes presently to be described. In such cases the lesion has been described as a rent, tear, ulceration, or perforation. The condition of the heart in the majority of cases of rupture has been already referred to in this article under the head of *Ætiology*. Echymoses are sometimes found in the vicinity of the lesion. The pericardium generally contains an effusion of blood, which often surrounds the heart with coagulum, leaving the sac filled with serum, to the amount, it may be, of thirty ounces, as in an instance which came under the writer's notice.

MECHANISM.—Rupture of the heart is doubtless nearly always the result of a strain or of pressure acting upon the muscular walls. The walls of the healthy heart are sufficiently strong to resist any ordinary force to which they are exposed. But when they are softened by degeneration, or are very thin, as is sometimes the case in the auricles or the right ventricle, they may give way before the pressure to which they are exposed during muscular efforts or strains, or even in the ordinary action of the organ. Thus, when a part of the wall of the heart is weakened by softening or other cause, this spot may be, as it were, torn across by the contraction of the healthy fibres among which it is situated. Or again, when the walls of the heart are thick, it may be that the outer surface, being strained over the contents of a distended ventricle, as would be the outer surface of an over-laid hoop,

gives way, tears, and the opening gradually extends from without inwards. These facts enable us to understand why rupture is more frequent in the left than in the right ventricle. A further explanation is to be found in the fact that the left ventricle is more frequently than the right the seat of fatty degeneration, from causes elsewhere alluded to (see HEART, Fatty Degeneration a.). There is yet another way in which softening leads to rupture. A softened spot occurs in the substance of the heart, and into it hæmorrhage takes place, constituting what is termed *apoplexy of the heart*. At times this hæmorrhagic softening may yield either externally or internally, and give rise to rupture. Lastly, the writer has seen more than once a small spot of softening with loss of substance occurring on the internal surface of the ventricular wall, most frequently in the left; this softening and breaking down of tissue gradually involves itself amongst the muscular fibres, until finally perforation of the outer wall of the heart occurs.

SYMPTOMS.—The symptoms of rupture of the heart may be described as those which are premonitory; and those which occur at the time of the accident. The former are such as indicate a diseased condition of the organ—namely, breathlessness on exertion, palpitation, more or less irregularity of pulse, and faintness. In some instances recorded these symptoms were so slight as hardly to attract attention, in others so severe as to cause intense suffering. In the majority of the cases noted in the table referred to, no mention is made of any preceding symptoms, death being sudden. In several cases it is distinctly stated that no symptoms preceded the fatal attack.

The occurrence of the lesion itself, when the patient has lived long enough to describe his sensations, has always been marked by intense cardiac suffering, more or less distress in breathing, restlessness, rapid and irregular pulse, faintness, pallor, coldness of the skin, sometimes vomiting, and by various nervous symptoms. When life is prolonged beyond a few minutes, there may be more or less intermission in the progress of these symptoms, but the whole attack is marked by anguish more or less severe. The duration of the attack itself from the first fatal seizure varies remarkably. In 71 out of the 100 cases alluded to, death was sudden, occurring within one or two minutes. One patient, however, lived eight days, 1 six days, 1 three days; 5 lived over forty-eight hours, 3 lived under twenty-four hours, and 19 under twelve hours.

The special symptoms indicative of a fatal seizure are, in addition to those already mentioned, severe precordial pain, dyspnoea, vomiting, cyanosis, pallor, loss of consciousness, and convulsions. These symptoms, or some of them, were noted in 44 out of the 100 cases; and in 34 of these the patient lived for more than five minutes after seizure, and in some of the cases for more than twelve hours. These cases, doubtless, are instances in which the muscular fibres are torn apart layer by layer successively. In the other 30 cases the patient was seized with severe pain, and then expired, or with

dyspnoea and some of the other symptoms mentioned above, and lived but a few seconds.

The physical signs of complete rupture having occurred, so far as can be ascertained, are merely—a greater or less amount of dulness in the region of the heart; the impulse diminished, the sounds muffled, distant, or imperfectly developed; and the pulse weak and intermittent.

COURSE AND TERMINATION.—The difference in the progress of the fatal malady depends much upon the seat of the rupture, on the size of the opening, and on the rapidity with which the extension of the laceration takes place. In the cases in which the septum is torn, there is no external hæmorrhage, and life is prolonged until the patient dies from disturbance in the functions of such an important organ as the heart. (See a case reported by Dr Peacock, *Pathological Transactions*, vol. v.) The progress of the symptoms is also influenced by the direction and course of the rupture. If the torn fibres overlap from the inside or from the outside, the injury penetrates slowly through the cardiac wall, and the fatal progress is also slow. (See cases recorded by the writer in the *Pathological Transactions*, vol. iii., and also in vol. xii.; and a case by Dr. Peacock in vol. xvii. of the same *Transactions*.)

PROGNOSIS.—As far as is known, rupture of the heart is always fatal. Still it is possible that such an accident, owing to the small size of the opening, its incomplete character, and its occlusion by a coagulum, may not prove fatal. Numerous instances are recorded of severe wounds of the heart, the subjects of which have survived. Ollivier has collected 29 such cases, only two of which proved fatal within forty-eight hours, the others living from four to eight days. Cases are recorded in which persons have survived many years severe wounds of this important organ. These cases, however, differ from those of rupture in this particular, that they occur in the healthy organ, whilst spontaneous rupture occurs in the heart when it is seriously diseased (see HEART, Wounds of).

TREATMENT.—In the way of treatment of rupture of the heart little can be done. The patient's sufferings may perhaps be relieved by the hypodermic injection of morphia, or by the use of other sedatives. Perfect rest should, if possible, be maintained.

R. QUAIN, M.D.

HEART, Softening of.—This term was formerly applied to several conditions of the heart in which the consistence of the cardiac tissue was diminished, whilst the process to which it was due was obscure or anomalous. It is probable that under the name of softening of the heart there were especially included instances of acute myocarditis, parenchymatous degeneration, and fatty degeneration. In the present more advanced state of cardiac pathology, it seems desirable that the expression "softening," while retained to express a familiar physical condition, should cease to be employed as a classifying term—that is, to designate any specific anatomical state.

J. MITCHELL BURN.

HEART, Syphilitic Disease of.—Syphilitic disease of the heart is by no means a rare condition, having been found in a large number of instances in which the specific nature of the lesion was determined with certainty; whilst, in another series of cases, similar anatomical appearances were present, although the existence of syphilis was not ascertained. Syphilitic disease of the heart is therefore of much pathological interest; but it cannot be said that a great deal is known as yet with respect to its clinical history.

Ætiology.—There appears to be nothing of importance known as to the causes of the localisation of syphilis in the heart. The congenital as well as the acquired form of the disease has been met with.

ANATOMICAL CHARACTER.—This morbid condition presents two leading appearances *post mortem*. The first is the well-marked syphilitic *gumma*, which closely resembles the same form of growth as it is met with, for example, in the liver and testicles. Gummata of the heart appear as pale yellow patches in the cardiac wall, or as yellowish nodules which are found on section. They present a variety of appearances, according to their age. When young they are firm or even scirrhoid; elastic, and homogeneous, creak on section; and are very slightly necrotic but when older, they become soft and elastic, like a mass of 'yellow tubercle.' In either form the masses are not isolated, but pass continuously into the myocardium, either directly, or through the medium of soft vascular connective tissue, so that they have generally been described in this country as 'infiltrations' or 'deposits.' The superjacent endocardium or pericardium is vascularised and dull in the early stage of the nodules, opaque and thickened in the more advanced. The masses or nodules occur in various numbers in different instances, but are generally multiple. They may be found in any part of the heart. Gummata most frequently become cancerous in the centre, as described, and they may then soften more completely and discharge inwards, leading to acute cardiac aneurism and ulcer of the wall, but more frequently the cheesy products are in a great measure absorbed, leaving a pitted or fibroid patch behind.

The second form of syphilitic disease of the heart is the *fibroid patch*. This is sometimes well-defined and localised, and in such instances it represents the stage of full development of an area of ordinary syphilitic interstitial inflammation. In other specimens, the fibroid patches appear as irregular masses of indurated fibroid tissue, occupying part of the wall of the heart, and sending septa into the depth of the myocardium, whilst the endocardium and pericardium that correspond to them are opaque, thickened, and puckered. The syphilitic nature of such patches may be determined by the presence of specific lesions in other viscera.

A form of the disease intermediate between the two forms just described is one in which the outer zone of the gumma has undergone development into fibroid tissue, and the caseous centre remains as a 'fibrinous' mass.

The microscopical characters of syphilitic growths do not require to be described here.

In the heart, the primary seat of the disease is the intermuscular tissue; the muscular fibres, lying imbedded in the gummatus products or in the fibroid growth being either healthy in appearance, or faintly degenerated and broken up.

Syphilitic endarteritis (*obliterans*) may also occur in the vessels of the myocardium, and give rise to infarction of the walls of the heart.

Amongst the occasional effects of syphilitic disease of the heart are chronic aneurism of the walls, distortion of the uteri and of the valves and their appendages, and, more frequently, adhesion of the pericardium. Some of the other viscera present, as a rule, evidence of syphilitic disease.

SYMPTOMS.—The subjects of syphilis of the heart may, from a clinical point of view, be divided into three classes. The first class of patients suffer from some one or other of the ordinary symptoms of chronic cardiac disease, such as dyspnoea, cardiac distress, palpitation, pulmonary complications, and general dropsy; whilst the physical signs are those of cardiac enlargement, and perhaps of valvular incompetence. Præcordial uneasiness, syncopeal attacks, and remarkable infrequency of the pulse, have been prominent features in several recorded cases.

The second class of subjects of this disease die suddenly, after few if any complaints referable to the heart.

The third class die of syphilitic marasmus, and may or may not present some evidence—by physical signs or otherwise—that the heart is not sound.

In many of the cases, other symptoms of visceral syphilis—for example, phenomena connected with the brain and nervous system—have been prominent.

DIAGNOSIS.—Well-defined symptoms or physical signs, such as those just mentioned, connected with the heart, occurring in a syphilitic subject, would, in the absence of other more probable causes, such as a history of endocarditis or Bright's disease, furnish considerable grounds for the diagnosis of specific cardiac disease.

PROGNOSIS.—If such a diagnosis were positively made, the prognosis would be more favourable than it is perhaps in any other form of chronic heart-disease, inasmuch as the condition might be successfully removed by treatment.

TREATMENT.—Anti-syphilitic remedies, especially iodide of potassium, should be freely tried, along with the other remedies indicated on general principles. J. MITCHELL BURN.

HEART, Thrombosis of.—**SYNON.**: Heart-clotting. Fr. *Thrombose cardiaque*; Ger. *Gerinnungen im Herzen*, *Herz-polypen*.

DEFINITION.—Coagulation of the blood within the cavities of the heart during life.

ÆTIOLOGY.—Thrombosis of the heart is most frequently due to local arrest of the movements of the blood, comparatively or absolutely, within its cavities. Such arrest is itself generally referable to weakness of the cardiac contractions, whether associated with dilatation secondary to valvular or pulmonary disease, or due to some primary affection of the muscular walls. The peculiar saccular condition of the extremities of

the auricular appendages, and the trabecular arrangement of the columns carnea of the ventricles, as well as the distance of the same parts from the main blood-currents, determine the favourite localisation of the thrombosis. Roughening of the endocardium is another cause of thrombosis, but one which is to be considered less common than the causes already mentioned, unless the fibrous conglua of endocarditis, or vegetations, be regarded as thrombi, which, in the strict sense of the term, they partly are. Possibly certain conditions of the blood may contribute to the occurrence of cardiac thrombosis. Finally, thrombi once formed tend to promote the further progress of the condition.

ANATOMICAL CHARACTERS.—Congula found within the heart are of two kinds, which have been termed *active* and *passive*, according as they are formed during life, or at or after death, respectively, and the characters of the former, with which alone we are here concerned, cannot be understood until those of the latter have been briefly described.

Passive conglua are found in the heart in most necropsies, occupying the track of the principal blood-currents. Frequently they appear as black or red blood-clots, occupying the auricles principally, and moulded in their cavities. In other cases they take the form of masses of firm whitish fibrine, cleaving with some tenacity to the endocardium, but not truly adherent; matted with the chordae tendineae and columns carnea, and projecting some distance into the pulmonary artery. Or, thirdly, passive conglua may be a combination of the two previous forms, the upper part (according to the position of the body) being decoloured or fibrous, and the deeper part resembling more an ordinary blood-clot. In certain cases these passive clots are peculiar. In phthisis and other diseases proving fatal by very slow exhaustion, they are remarkably firm and fibrous, and closely matted amongst the chordae tendineae—appearances which seem to indicate that coagulation was slowly proceeding for some time before the heart had finally ceased to beat. In anaemia they are jelly-like and translucent. In leukaemia they are soft and creamy in appearance, and yield, when broken up, a puriform fluid. In the acute exanthemata these passive clots are soft and friable, and in many cases of those and of other forms of acute disease and of sudden death, no conglua are found in the heart, which contains only fluid blood.

Active conglua—the result of thrombosis of the heart—are, on the contrary, situated in the auricular appendages of the auricles, at the apex of the ventricles, and in the recesses behind and between the columns carnea—in other words, as far as possible from the track of active blood-currents. In these situations they may be seen projecting in the form of fleshy knobs or globes, with their free surface smooth and rounded. Their deep surface is adherent to the endocardium, from which, however, it can generally be separated without much difficulty, leaving behind it a discoloured mark. If the thrombus be incised, it will be found to be laminated in structure, somewhat after the fashion of an onion, the outer of thesection being greyish-

brown or yellowish, with irregular patches of red and black. In most instances the centre is less firm than the periphery; and usually it is of a fluid consistence, in the form of a foul, sanious, puriform substance.

If the process of thrombosis have been proceeding for some time, these formations may extend in all directions, embrace the columns carnea, enclose in front of them, and finally may fill up a considerable portion of one, or even of more than one, cavity. The thrombi are generally friable; but sometimes they gain in firmness by the deposit of lime-salts within them, and at other times it is possible that they become detached and form into the 'fibrous balls' which have occasionally been found lying free in the cavities of the auricles. Cardiac thrombi may, in part at least, be resorbed. They frequently give way during life, and portions of them, as well as of their puriform contents, are conveyed into the circulation, causing embolism and pyemia.

It may be added that *embolism* of the heart has frequently been found—thrombi or simple clots, sometimes of remarkable size, having been carried from the veins, and arrested in the heart or in the mouth of the pulmonary artery.

SYMPTOMS.—The clinical phenomena associated with true cardiac thrombosis may be best described as those of the last stage of chronic disease of the heart. Precordial distress and restlessness, irregularity and feebleness of the pulse; oedema and coldness of the extremities; pulmonary congestion, infarction, and oedema; dulness of expression, and sopor, broken by low weak delirium, with other symptoms, as well as with the signs of cardiac failure and imperfect emptying of the cavities in systole—all these phenomena are associated with the process of active coagulation within the heart. It would not, however, be correct to describe these phenomena as symptoms directly referable to the thrombosis. All that can be said is that in such a case thrombosis is probably going on and increasing the embarrassment and the gravity of the condition. An unusual degree of cyanosis appears in some instances. The symptoms of arterial embolism may suddenly make their appearance from detachment of particles of the clots; and, if the puriform contents find their way into the circulation, septicæmia may result.

The dislodgment *en masse* of a large venous thrombosis, and the impaction of the same, or of a 'fibrous ball,' in one of the ostia of the heart have caused sudden death in several cases.

Passive coagulation.—It should be added that the appearance of the 'passive' form of coagulation within the heart, which has been already referred to as a post-mortem process, or one occurring in *articulo mortis*, has been otherwise interpreted by some authorities, who regard passive conglua as formed *ante mortem*, and as giving rise to severe symptoms by the embarrassment which they produce in the circulation. The symptoms caused by this condition are said to be—great precordial pain and distress; tumultuous action of the heart, passing on to irregularity, flickering, and finally arrest, whilst the pulse is very feeble; urgent dyspnoea; cyanosis;

HEART, THROMBOSIS OF.

hemoptysis; coldness of the extremities; deepening stupor; and coma ending in death—in short, the congeries of symptoms which would be referred by most authorities to failure of the muscular walls of the heart, the coagulation being regarded by the latter as only another result of the same condition.

DIAGNOSIS.—In the presence of the very serious and complex conditions with which cardiac thrombosis is usually associated, the question of its existence can hardly be said to occur to the physician as a point of great importance. An unusual degree of cyanosis, especially if it be progressive, favours the recognition of this state; and in the absence of valvular disease, the occurrence of embolism or pyæmia would tend to confirm it.

TREATMENT.—The treatment of cardiac thrombosis consists in the treatment of its cause, and nothing is demanded or can be done for the former which is not indicated for the relief of the latter.

Those authorities who see in 'passive' conglutination the evidence of rapid *ante-mortem* thrombosis, recommend the use of stimulants, and even of certain drugs which are supposed to have a solvent effect on fibrinous deposits, especially ammonia.

J. MITCHELL BRUCE

HEART, Tuberculosis of.—Independently of the pericardium, the heart itself is believed to be rarely the seat of tubercular disease. Grey milky tubercles have been found in the connective tissue of the wall of the heart, in some cases of acute general tuberculosis. In other instances the 'tubercle' has been of the yellow or cheesy kind, in the form of small nodules lying at various depths in the muscular tissue beneath the pericardium, the latter also being frequently affected, as well as the lungs, intestines, and other organs.

There appears to be no evidence that tuberculosis of the myocardium gives rise to definite symptoms, or that it can be recognised during life.

J. MITCHELL BRUCE.

HEART, Valves and Orifices of, Diseases of.—**CLASSIFICATION.**—The diseases of the valves and orifices of the heart which produce mechanical disorders of the circulation, by establishing abnormal relations between those parts, are of two kinds—*obstructive* and *regurgitant*. Valvular disease, on the one hand, is said to be *obstructive* when narrowing of an orifice presents an obstacle to the passage of the blood-current—a condition better named *stenosis*. On the other hand, when the blood regurgitates or flows back through an orifice, in consequence of imperfect closure of the valves, due either to valvular changes or to widening of the orifice, the condition is called *regurgitation* or *insufficiency*.

Aneurism of the valves of the heart will be discussed separately. See HEART, Valves of, Aneurism of.

ÆTIOLOGY.—Each of the orifices may be affected with one or both forms of disease, but the frequency with which the several orifices are attacked varies. The results of organic disease are chiefly met with in the left side of the heart, and are due to local inflammation—endo-

HEART, VALVES OF, DISEASES OF.

carditis and its consequences; or to chronic degenerative changes, such as atheroma. In adult life the valves of the left side are more frequently affected than those of the right, because they have to bear a much greater pressure; but in fetal life, when the condition is reversed, the right valves suffer more. Endocarditis is commonly of rheumatic origin, and attacks the mitral more frequently than the aortic valves, the former having to sustain the full force of the ventricular systole, while the latter only bear the force of the aortic recoil. In addition to rheumatic fever, the chief diseases which tend to develop endocarditis are—pyæmia, puerperal fever, the exanthemata, chronic renal disease, and syphilis. The aortic valves are more commonly affected than the mitral by chronic endarteritis extending from the aorta, the chief causes of which are gout, old age, syphilis, and the abuse of alcohol. These facts explain why mitral affections (commonly rheumatic) occur mostly in early life, and aortic affections in later life. Valvular lesions are more common in men than in women, from the strain of the heart incidental to more laborious occupations. Strain helps to swell the greater proportion of discus of the aortic valves, which are liable to rupture from effort; but similar accidents may occur to the mitral valve and its tendinous cords.

ANATOMICAL CHARACTERS.—The pathological changes in the valves and orifices of the heart, which cause valvular defects, are mostly the results of acute or chronic endocarditis. In the acute form, the valvular defect is caused by the growth of vegetations which prevent the action of the valve-segments; or by softening and ulceration of the valve-structure, which lead to valvular aneurism and perforation, or to loss of substance and consequent insufficiency. The more chronic form of inflammation produces thickening of the valves from overgrowth of the connective tissue, with subsequent calcareous degeneration and retraction from shrinking of the hyperplastic connective tissue, or adhesion of the valve-segments causing stenosis.

Aortic stenosis is generally the result of thickening and calcareous degeneration of the valves, or of deformity of the valves from vegetative growths, which obstruct the free passage of the blood from the ventricle. Sometimes it is due to adhesion of the valves preventing their elevation, and causing them to form a diaphragm with a narrow central aperture. More rarely it is caused by contraction of the fibrous ring of the aortic orifice, or by endocardial thickening producing contraction immediately beneath the valves.

Mitral stenosis results most frequently from thickening and rigidity of the valves, which adhere at their edges to each other, so as to form a diaphragm between the auricle and the ventricle. This diaphragm is usually funnel-shaped, with a button-hole aperture sometimes not larger than a goose-quill. In these cases the tendinous cords of the valve are shortened, and their muscles thickened. In some cases the valves are smooth and thin; in others they are thickened, studded with vegetation, rough and calcareous. The latter state may cause stenosis.

without any funnel-formation, as may also fibrinous clots or polypi obstructing the orifice. In many cases of mitral stenosis, the valves are also insufficient.

Aortic insufficiency often depends on dilatation of the aortic orifice, due to softening of the aortic coats, with little or no change in the valves, which are incapable of closing the enlarged orifice. Vegetations, thickening, retraction, calcareous degeneration, adhesions, perforations, loss of substance, and rupture of the valve-segments by effort are all causes of aortic insufficiency. In rupture of the valves, a full description of which was first given by Dr Quain (*Edin. Monthly Journ.* 1846), the valve-segment is torn from its angles of attachment, and its free edge retroverted towards the ventricle. This accident happens more frequently in cases where the valves were previously diseased, and in such cases further laceration may occur.

Mitral insufficiency is due to thickening, retraction, or deformity from vegetations of the valve-curtains; adhesion of the curtains to each other or to the ventricular wall; and calcareous degeneration. In some instances, one of the valves is perforated or torn; and sometimes the tendinous cords are shortened and thickened, or ruptured as the result of degeneration, preventing the normal action of the valve curtains. In rarer cases associated with dilated ventricle, the papillary muscles are so weakened by degeneration that they can no longer aid in the closure of the orifice. Dilatation of the left auriculo-ventricular orifice is also a cause of mitral insufficiency.

Valvular defects on the right side of the heart are due to similar changes. They arise chiefly during fetal life, when the right cavities have to bear greater pressure. In adult life these defects are generally associated with diseases of the lungs, which cause increased tension in the right cavities, leading to their dilatation.

Combined valvular lesions are not infrequent. The most common are stenosis and insufficiency of the aortic valves, and the same morbid changes of the mitral valves. In the last stages of both forms of aortic valve-disease, the mitral valve becomes insufficient, either from chronic endocarditis, or from dilatation of the ventricle and of the auriculo-ventricular orifice. Mitral stenosis is not very frequently associated with aortic insufficiency, but is more commonly connected with some degree of narrowing at the aortic orifice. Tricuspid insufficiency is usually met with in the last stages of diseases of the left heart.

Symptoms.—Valvular diseases of the heart produce a series of morbid phenomena, which are connected together by a necessary sequence. Each and every form of valvular defect impairs the perfection of the heart as a pumping machine, and disturbs the normal relations between the contents of the arteries and of the veins. Wherever the valve-mischief is, and whatever its nature, it robs the arterial circulation and enriches the venous. In front of the lesion there is less blood; behind it there is more. In aortic valvular diseases, the first effects are increase of the blood-pressure in the left ventricle, and lessened blood-pressure in the aorta; next from the difficulty which the auricle has in emptying

all its contents into an overful ventricle, there is produced increased pressure in the left auricle and pulmonary veins. Mitral valve-lesions cause similar results. First, increased pressure in the left auricle, less pressure in the left ventricle, and consequently lessened pressure in the aorta; with a gradual increase of pressure extending from the left auricle to the pulmonary veins. Aortic affections thus act first on the arterial, and secondly on the pulmonary circulation. While mitral lesions affect the pulmonary vessels more immediately. The final results of the two forms are, however, identical, and may be stated in the form of a law, namely, that all valvular diseases of the heart tend to lessen the quantity of blood in the arterial system, and to produce overfulness and stasis in the veins. From this there follow various associated visceral disorders. These disorders, however, vary greatly in the period of their occurrence, and in the intensity of their manifestations. This result is due to the more or less perfect way in which the original valvular defect has been compensated for, by changes in the power of the cardiac muscle and in the capacity of the cardiac cavities. These changes often suffice to maintain fairly the normal balance between the arterial and venous contents, thus *compensating* for the valve lesion, and the process by which this is effected demands careful consideration.

Compensation.—Compensation is effected differently, according to the form of disease. It may be stated generally, that it consists in hypertrophy of the cavity immediately behind the defect. Now hypertrophy means increased contractile power, and this means better filling of the arteries, and consequently increased arterial tension. Thus it makes up for the valvular incompetency, which tends to lessen arterial tension. When the increased power of the ventricle exactly balances the effects of the valvular mischief, the compensation is complete.

In *aortic stenosis*, hypertrophy of the left ventricle is the mode in which compensation is effected; the obstacle to the blood-current is overcome by increased power.

In *aortic insufficiency* there is some dilatation of the ventricle as the primary result of the lesion. This is counterbalanced by greater hypertrophy, and as long as the dilatation does not progress, the insufficiency is compensated for. A sufficient excess of blood is thrown into the aorta at each systole to allow for the regurgitation during each diastole, and thus the balance is maintained, though not always equally.

In *mitral lesions* the left auricle is dilated as the primary consequence of the condition of the valves, hypertrophy follows, but is insufficient to prevent increased fullness of the pulmonary veins. This impedes the circulation in the lungs, and increased tension in the pulmonary artery soon begets the necessary hypertrophy of the right ventricle. It is by means of this increased power of the right ventricle, that the blood is driven through the lungs in spite of the defect in the left heart, and pulmonary stasis is prevented; and the blood entering the left auricle under greater *vis a tergo*, the compensation of the valvular defect is effected. The compensation, from the nature of the means on

which it depends, is manifestly less perfect than in aortic lesions.

On the *right side of the heart* similar modes of compensation are observed.

The basis of the salutary changes just described is increased cardiac nutrition; and consequently a free coronary circulation is a necessity. Conditions which interfere with this prevent compensation, and so diminish the duration of life. Wherever the compensation begins to fail, dilatation of the cavities and vessels behind the lesion commences. This may, however, be checked, and the power of the heart restored for a time. Sooner or later, however, changes in the nutrition of the cardiac muscle, in the vessels, and in the general nutrition, bring on failure of compensation. The cardinal symptom in such cases is weakened contractile power of the heart, or *asthenia* (Beau). In this state, the cavity chiefly affected has no longer power to expel its contents fully into the vessels, and consequently becomes gradually and increasingly distended. Failing compensation in aortic valvulose disease manifests itself by dilatation of the left ventricle, and the development of secondary mitral insufficiency. Similar retro-dilatation marks the failure in mitral cases, only here it is the right ventricle which dilates, and tricuspid insufficiency and general venous stasis are added to the pre-existing pulmonary engorgement.

The earliest symptoms of failing compensation are attacks of palpitation from very slight exertion or excitement, or during sleep. Irregularity of the pulse soon follows, if it have not previously existed. This is especially the case in mitral disease. The irregularity is due not so much to true cardiac intermission as to abortive contractions, which do not reach the wrist; or to contractions unequal in force or in the quantity of blood expelled. The pulse is small, unequal, irregular, and compressible. In aortic valvular disease true intermissions occur, and are of grave import. With failing cardiac power there usually supervenes cardiac oppression, anginous attacks from distension of the cavities of the heart, and faintness and giddiness from cerebral anæmia.

Visceral complications.—The most important of the associated disorders of chronic valvular disease, depending on defective contraction of the heart, are the visceral congestions.

In the *lungs*, the habitual engorgement of mitral diseases produces a hyper-secretion of mucus and a state of chronic catarrh. The blood-vessels also undergo changes from the excessive intra-vascular pressure, and become dilated, varicose, and atheromatous: whence œdema and hæmorrhage arise. In mitral stenosis especially, grave and frequent attacks of hæmorrhage, with laceration of the pulmonary substance, are liable to occur. The lungs, from repeated attacks of this kind, undergo brown induration. The varicose condition of the vessels in the alveoli interferes with oxidation, and so aids in the deterioration of blood, which the other visceral congestions favour.

In the *liver*, the general venous stasis is felt by the obstruction to the passage of blood from the hepatic veins into the inferior cava. Passive congestion ensues, and 'nutmeg liver' results.

This term 'nutmeg liver' refers to the rough changes in the viscous, the dark congested centre of each lobule being surrounded by a paler area. In course of time the compression of the central cells of each lobule by the distended veins leads to atrophy; the liver, from being large, shrinks in very chronic cases to half its size; and the condition may, like true cirrhosis, lead to ascites. The passive congestion in the liver, as in the lung, causes catarrh of the tubes, and may thus be productive of jaundice. Amongst other symptoms associated with the hepatic congestion may be mentioned hæmorrhoids and epistaxis.

The *spleen* is a very easily distended organ, and suffers like the liver, but frequently before it; and this may partly account for the pain which is often complained of beneath the left ribs. In long-standing cases the spleen becomes tougher, and the capsule opaque and thickened; while hæmorrhagic infarcts are common.

From the hepatic congestion there naturally follows distension of all the other radicles of the portal vein: hence the congestion and chronic catarrh of the *stomach* and *intestines*, which impedes digestion and assimilation, and so reinforces the other causes producing the cachexia of chronic valvular disease.

In all cases of valvular disease, when the mechanical effects extend to the general circulation, the function of the *kidneys* is more or less disordered. The first stage of general circulatory trouble is lessened arterial tension; this makes itself felt in the Malpighian tufts, and is manifested by scanty, dense, high-coloured urine. When the more advanced circulatory trouble—namely, general venous stasis—is developed, a further change takes place in the urine. The arterial anæmia keeps it still scanty and dense, but the venous stasis in the kidney leads to the transudation of serum—a dropy of the kidney as it were; and consequently albumen appears in the urine. Long-continued venous congestion ends in structural changes, which, as elsewhere, consist in connective-tissue hyperplasia and degenerative (rarely fatty) changes in the tubules. These renal changes sometimes add uræmia to the patient's ailments.

In the *bræia*, decided alterations are not found, except when a detached vegetation produces embolism and its special phenomena. The brain-substance is, however, generally œdematous, and the membranes are thickened. Delirium is an occasional symptom in heart-disease, and when present to any degree is of evil import. The blood-vessels of the general circulation are frequently affected with atheroma in hypertrophy of the left ventricle, and it is these degenerative changes which favour the occurrence of apoplexy.

General dropy.—The mechanical impediments to the circulation which produce these several visceral congestions, also manifest themselves in the general dropy which is common in the last stages of heart-disease. The dropy begins as a puffiness of the ankles at bed-time. The general venous stasis, thus first indicated, advances slowly and surely, if not checked, to general anæmia, and even to dropy of the serous cavities. The increased venous tension, and the hydrops of blood-deterioration, are

the oedema of this *serre* transudation, which shows itself first in the feet, the most dependent portions of the body, where the pressure of the blood-column is naturally greatest. The horizontal posture, by distributing the pressure, is sufficient at first to disperse the oedema of the ankles. General anasarca is much more frequent in mitral than in aortic lesions.

In some cases a solid form of oedema is observed. This occurs mostly in the last stages of valvular affections, and is due to thrombosis of venous trunks, in which, the circulation being much impeded, coagulation easily takes place. The termination of the external jugulars is a common site for such thrombosis; and the left innominate vein, from its transverse position, and from its emptying almost at right angles to the current in the superior vena cava, is, in the writer's experience, more commonly obstructed than the right. Solid oedema is consequently seen more frequently on the left side of the head and neck and in the left arm, than on the right side.

Defective compensation.—The phenomena just described are associated with valvular diseases of the heart, as the consequences of partial or defective compensation. These conditions are more or less developed according to the individual case, and consequently give rise to symptoms in varying degrees. These symptoms will now be described.

Palpitation is intimately related to the state of cardiac nutrition and innervation, and has no special connection with any form of valvular disease. Cardiac pain, varying in intensity from mere uneasiness to the agony of angina, is most common in aortic cases, and is associated with endarteritis, or with dilatation of the left ventricle, or is a neuralgia of the cardiac plexus. In mitral affections, pain arises from over-distension of the left auricle, and its pressure on neighbouring parts, and later on from dilatation of the right ventricle. Dyspnoea may be present in any form of valvular disease, but it is often absent from the earlier history of aortic cases, while some dyspnoea is always present in mitral cases. This difference is due to the absence of pulmonary congestion in aortic affections, whilst it is more or less present from the first in mitral affections. The dyspnoea is a breathlessness rather than a difficulty of breathing. It is panting and gasping in its character, with acceleration of the rate. It is aggravated by any movement, and often compels the patient to sit upright (orthopnoea). Headache, vertigo, dreaming, night-frights, and sleeplessness are other symptoms, which depend on disordered cerebral circulation. Sleeplessness is one of the most distressing of all symptoms, and can only be relieved when the dyspnoea is lessened. Other more special symptoms will be found in certain cases, and will be traceable to the disturbances in the circulation, which the particular form of valvular disease has engendered.

Physical signs.—The physical signs associated with valvular affections may be said to be—first, those of alteration in the size of the heart; and secondly, those of mechanical disorders of the circulation; together with one or more *cardiac murmurs*. The persistence of a

murmur is the cardinal sign, and if two murmurs be either diastolic or presystolic in its rhythm it is of absolute value. A systolic murmur may be caused by poverty of blood—anaemia, especially at the base of the heart. But in such a case—that is, in hæmic murmur—there is no cardiac hypertrophy, as indicated by increased cardiac dullness, though there is often nervous overaction of the heart. There is no accentuation of the pulmonary second sound, inasmuch as there is no extra fullness of the pulmonary blood-vessels from obstructed circulation. The pulse in anaemia is generally quick, ample, and compressible, but, withal, jerky, while with an organic systolic murmur it is generally slow, rising gradually under the finger, and not very compressible, (aortic stenosis), or small, irregular, and unequal (mitral insufficiency). The clinical methods of investigating valvular lesions are mainly inspection, palpation, percussion, and auscultation. The signs of each form of valve disease are stated below; and on these the special diagnosis rests.

DIAGNOSIS.—In *Aortic stenosis* there is often some prominence of the præcordial region, and a steady forcible impulse is perceived below and to the left of its normal position. A thrill, systolic in time, may often be felt at the base of the heart. On auscultation, a loud, frequently rough, rasping, sometimes musical, murmur is heard with the first sound at mid-sternum, and also at the second right intercostal space. The murmur, commencing with the first sound, extends to the succeeding second sound, which is often not very distinct. The murmur is audible all over the upper part of the thorax, especially on the right side, is conducted along the great vessels to the left vertebral groove, and it may be even to the lower dorsal vertebrae; and is occasionally heard at the apex of the heart. The pulse is regular, slow, retarded by the narrowing of the aortic orifice, and slowly developed under the finger. The sphygmogram (see fig. 82) shows the line of ascent to be oblique or broken, instead of nearly vertical; the summit is generally blunt, and the line of descent shows small or no secondary waves, and ill-developed dicrotism. Aortic stenosis when moderate, requiring only hypertrophy of the left ventricle for its compensation, is often very perfectly remedied by this change, and produces little or no disorder of the circulation. When the stenosis is great, epileptiform and syncopal attacks may occur, and lead to sudden death. When the compensation fails, the mitral valve often yields, from the dilatation of the left ventricle, and degeneration of the papillary muscles. Then the pulmonary second sound becomes accentuated; the pulmonary circulation is embarrassed; and dyspnoea, bronchial catarrh, pulmonary hæmorrhage, oedema, and cyanosis supervene.

In *Aortic insufficiency*, inspection discovers a more forcible and diffused impulse, lower than natural, sometimes as low as the seventh intercostal space, and outside the nipple line. The præcordial region may be bulging from the violent action of the heart; pulsation may be seen in the upper intercostal spaces at the right edge of the sternum; and a thrill may sometimes be felt there. The great vessels of the neck

pulsate visibly. The area of cardiac dulness is increased in all directions, but mainly vertically. On auscultation, a murmur is heard, replacing and following the second sound, of a blowing or hissing character, rarely rough. It is usually loudest at mid-sternum and in the second right intercostal space; and it is conducted upwards to the right clavicle, but mainly downwards to the xiphoid cartilage. It is not heard at the back of the chest. It may be conducted to the apex of the heart rather than to the ensiform cartilage; and this occurs, in the writer's opinion, when the posterior or mitral segment of the aortic valves is the incompetent one, as the regurgitant current then falls on the mitral valve, and the murmur is thus conducted to the apex. The second sound may be wholly lost at the base of the heart, being replaced by the murmur; but in some cases it is audible—this being due either to normal closure of one or two aortic segments, or to the propagated pulmonary second sound. If audible in the carotids, the second sound is aortic, and is of some value as indicating partial competency of the valves. The second sound is often audible at the apex. The first sound at the base is almost always modified, being generally murmurous and often obscured by a systolic murmur, due to slight obstruction from thickening of the valve-segments, and the vigour of the ventricular systole. In some cases there is no distinct first sound audible at base or apex, its absence being possibly due to noiseless closure of the mitral valve by the intra-ventricular blood-pressure before the systole occurs. In the majority of cases the insufficiency is no doubt associated with some stenosis, and the murmur is double; a short rough systolic portion, with a softer, longer, and more hissing diastolic portion. This double murmur might be well called the *up* and *down* murmur of aortic valve-disease: the two descriptive words indicating the length, and, to some extent, the characters of its component parts.

The signs connected with the pulse in aortic insufficiency are very significant. As the pulsations of the aorta are visible to the right of the sternum, so the arteries often beat visibly all over the body, even to the radial, temporal, and dorsal arteries of the foot. The ophthalmoscope has shown the same phenomenon in the central artery of the retina. This remarkable movement of the arteries is due to two causes:—first, to the hypertrophy and dilatation of the left ventricle, which throws an excessive quantity of blood into the vessels at each systole; and, secondly, to the sudden collapse of the arteries, due to the aortic insufficiency. The arterial recoil during the ventricular diastole is not opposed, as in health, by the resistance of the perfectly closed aortic valve; and, consequently, the blood-column is not sustained, and the arteries collapse. These locomotive features in the pulse are generally increased by elevating the arm. The pulse is sudden, short, large, regular, rapidly collapsing, and vibratory. The sphygmographic tracing brings out these characters: the line of ascent is vertical and lofty; the summit is sharp and pointed; the line of descent falls rapidly, and is broken by a series of secondary waves due to vibratory conditions, but has an ill-developed

dicrotism. The post-dicrotic portion of the tracing falls rapidly, from the absence of a sustained blood-column. The longer and more oblique this portion of the tracing, *ostens peritunc* the less copious the regurgitation (see fig. 81).

Aortic insufficiency often lasts for many years without producing any obvious disturbances of the systemic and pulmonary circulations; hence the absence of dyspnoea and oedema. The hypertrophy and dilatation of the left ventricle, which form the compensation, suffice to prevent ill effects. At each systole the dilated ventricle throws sufficient blood into the aorta to allow for the reflux, and to maintain a fair arterial tension. Thus the compensation is perfect. In many cases, however, if the reflux is free, and the coronary segments of the aortic valves are affected, the coronary arteries, which are mainly filled by the arterial recoil, are deprived of the full force of the blood-wave, and the nutrition of the heart consequently suffers. This is the great source of failing compensation, and the mal-nutrition of the cardiac muscle soon leads to dilatation of the ventricle, secondary mitral insufficiency, and atrophy.

When the hypertrophy is excessive, as it is in some cases, there are flushings of the head and face, headache, vertigo, and violent arterial action all over the body.

In *Mitral stenosis* there is rarely any prominence of the precordial region; and in its earlier stages neither increase of the cardiac dulness, nor alteration in the position of the impulse. The impulse, when regular, is fairly distinct, but it is often very irregular and is associated with a thrill, which precedes, runs up to, and terminates in the impulse. In advanced cases, the area of cardiac dulness is increased laterally; the impulse is diffused, and may be seen in the epigastrium; and the left auricular systole may be noticed, if the chest be thin, in the third left intercostal space. The sounds heard on auscultation in this lesion vary. The pathognomonic sign is a murmur preceding the systole, and ending with its commencement. This is best called the *presystolic* murmur (also 'auricular systolic'); and is produced when the contracting auricle forces blood under high pressure into the ventricle. It is the passage of a stream of blood in a state of high tension into blood already in the ventricle which causes the murmur. The first portion of the blood passes from the auricle into the ventricle noiselessly; and it is only when a stream of higher tension is forced into it by the true auricular systole that the murmur is developed. The murmur is, therefore, short in most instances, occupying the last part of diastole; runs up to the first sound; and ends abruptly in it. The position in which the murmur is best heard in its typical *presystolic* form is at the left apex itself or a little above—that is, lower than a mitral regurgitant murmur. The funnel-like shape of the mitral valve-cartilages in these cases accounts for this, as the button-hole aperture through which the blood passes is closer to the apex.

The murmur in this form is not heard far from its seat of production, is soft and puffing, but may be harsh. It fills commonly only the last part of the diastolic period. In some cases the murmur is

longer, rougher, more rolling or grinding, and ends abruptly with the first sound, which is very flapping in tone, and might easily be mistaken for the second sound conducted. The careful observation of the impulse or of the carotid pulse with the finger while auscultating, is necessary in order to avoid the error.

A special peculiarity of the pre-systolic murmur is its variability: it is the only organic murmur which disappears and reappears as the heart-conditions change. For instance, a murmur, inaudible while the patient is at rest, is developed by a little exercise; or again, an irregular tumultuous action of the heart masks all murmur, which becomes distinct as the heart settles down under the action of digitalis. In other cases there is no distinct murmur, but only a slightly prolonged and rough or grinding first sound. In cases of mitral stenosis there is accentuation of the pulmonary second sound, from the greatly increased tension in the lesser circulation; there may also be a doubling or reduplication of the second sound at the base. This reduplication is a sign of great value in cases in which the prolonged or grinding first sound is the only sign. The reduplication of the second sound is due to a want of synchronous closure of the pulmonic and aortic valves, from their altered relative tension. A doubling of the first sound is sometimes noticed, probably due to retarded closure of the mitral valve, from lessened fulness of the left ventricle.

The rhythm of the heart is frequently greatly disordered in mitral stenosis, and also in mitral insufficiency. A few beats occur regularly, or nearly so, and then a series of very small hurried ones follows, to be again succeeded by stronger and better pulsations. These irregularities are referable to the varying charges of blood on which the ventricle contracts. The over-distended right cavities and the left auricle contract rapidly to expel their contents, but the narrowed mitral orifice does not allow a full charge to pass into the ventricle; the diastole is too short for this purpose; and the wave of contraction passes on to the ventricle from the auricle, producing a series of small ineffective pulse-beats, each representing the small charge sent into the aorta. When the series of ineffective contractions ceases, the next diastole is longer; and the succeeding systole sends, as the sphygmograph shows, a fuller charge into the arteries. During the small irregular beats the pre-systolic murmur is often undistinguishable, but is again heard with the succeeding slower and more effective beats. This irregularity in the heart's rhythm, however, is not present in all cases of mitral stenosis. In some instances the heart's action and the pulse are regular. The sphygmograph in such cases records a small pulse of low tension, with a little inequality in the volume of the beats; this inequality is often increased by exercise. In other cases the pulsations are small, irregular, and unequal in its pulsations, and marked by true and false intermissions (see fig. 84).

In the earlier stages of mitral stenosis the face may be pale, and the congestive symptoms which mark mitral insufficiency are absent till the later stages. This form of valvular lesion gives rise

more commonly than mitral insufficiency to hæmorrhagic infarction in the lungs; but in other respects the pulmonary and systemic circulations suffer in the same way as described in the other form of mitral disease.

In *Mitral insufficiency* inspection discovers some slight prominence of the præcordial region, with increased impulse, the apex often beating to the left of the nipple line. The area on cardiac dullness is augmented mainly in a lateral direction, from the hypertrophy of the right ventricle. On auscultation, a murmur is heard with the first sound, and following it; loudest at the apex; loud along the left edge of the heart; but absent or not so distinct over the right heart and at the base. The murmur is propagated towards the left axilla, and is audible in most cases in the left vertebral groove. The murmur is usually loud, blowing, and distinct in its character, keeping the same tone throughout. The true first sound is generally obscured by it, but in some cases may be heard through it, and is then due to the partial closure of the mitral, or to the action of the right auriculo-ventricular valves. The pulmonic second sound is commonly accentuated. The pulmonic first sound has in some cases a murmurish character, due probably to the vigour of the right ventricular systole.

The radial pulse in cases of fairly perfect compensation is regular, but quick, small, weak, and easily compressible; and the sphygmograph shows low tension, and an inequality in the size of the pulsations. In cases of less perfect compensation, it becomes irregular and intermittent. In all cases the pulse-beat is weak in comparison with the vigour of the ventricular systole (see fig. 83).

There is no unusual fulness of the superficial veins in the earlier stages of mitral insufficiency. Later, when the right cavities become over-distended, the veins of the neck become full and may even pulsate. This is very distinct when the tricuspid valve gives way. In all cases slight exertion is sufficient to induce dyspnoea; and there is an ever-present tendency to bronchial catarrh, from the congested state of the lungs. When systole comes on, the murmur becomes less distinct; the heart's action is rapid, irregular, and tumultuous; the accentuation of the pulmonary second sound is lost; dyspnoea becomes orthopnoea; and cyanosis, oedema, and hæmorrhagic infarction of the lungs, with general and visceral dropsy close the case.

Many cases of mitral regurgitation obtain fairly perfect compensation; but the disease, like mitral stenosis, of necessity entails some dyspnoea on exertion, and keeps up constantly an engorged state of the pulmonary vessels.

Valvular affections of the right heart, arising from disease, are rare. Those of the *pulmonic valves* are very rare; cases are on record, however, of pulmonary stenosis, and a few of pulmonary insufficiency. In the first case the systolic murmur is loud and superficial, and is heard loudest at the third left costal cartilage close to the sternum, and in the second left intercostal space; it is not usually conducted across the sternum, nor upwards to the right clavicle, as is an aortic murmur. A diastolic pulmonic murmur is soft and blowing; and is heard loudest

in the same situation, and downwards towards the ensiform cartilage.

The *tricuspid* valves are more frequently affected. Tricuspid insufficiency is indeed a common sequence of disease of the left side of the heart. Structural changes in these valves are, however, rare. Tricuspid insufficiency does not always produce a murmur; when present this is soft and short, and is heard nearer the middle line than a mitral murmur, at the base of the ensiform cartilage. The pulsations of the cervical veins may indicate the lesion when the murmur is absent.

Tricuspid stenosis causes a *præ-systolic* murmur, harsh in character, loudest at the base of the ensiform cartilage and towards the left edge of the sternum, not propagated towards the left heart, and not audible at the back of the chest, though faintly conducted along the sternum to the base of the heart. A *præ-systolic* thrill may be present. Mitral stenosis has been observed in association with this lesion, and two *præ-systolic* murmurs may be made out in such cases.

The physical signs and the diagnosis of combined valve-lesions remain to be described. The mitral and aortic valves may each be affected with stenosis and insufficiency, from a single attack of endocarditis, or from one lesion arising as a consequence of the other. The double aortic murmur, above described, indicates the aortic combination; but it must be always remarked that the systolic murmur in these cases may exist with little or no actual stenosis.

In the double form of mitral disease, either defect may exist alone at first, and afterwards be associated with the signs of the second. In some cases the *præ-systolic* murmur may fail to be heard, and a systolic murmur may alone be audible; in other cases, there is a prolonged apex-murmur which slightly changes tone; in other cases, again, a short grinding *præ-systolic* murmur is followed occasionally, at an interval, by a soft, blowing, systolic one. The combination of aortic with mitral disease may be recognised by the presence of their special murmurs.
